The case study is a typical short span overpass with two lanes, currently under investigation within the European Project SEQBRI (Paolacci et al. 2016). The bridge is 40.00m long and consists of 2 spans of 20.00m each.

Based on PEER strong ground motion database, a suite of ground motion records has been selected, which includes 60 near-fault (NF) pulse-like ground motions and 60 far-field (FF) ground motions. Two hazard conditions are adopted to select NF ground motions: moment magnitudes (MW) greater than 6.0 and site-to-source distances (R) less than 20 km (Stewart et

al. 2002; Bary and Rodriguez-Marek 2004). Additionally, the dimensionalized peak ground velocity (PGV) and peak ground acceleration (PGA) were imposed to be greater than 0.2 (Kwon and Elnashai 2006; Padgett 2008; Zhai et al. 2012). The FF ground motion records were selected to match the PGA and MW of the NF records, but with  $R > 20$  km. The selected NF ground motions were recorded during the following 5 strong earthquake events: Imperial Valley Earthquake (America, 1979), Palm Springs Earthquake (America, 1986), Northridge Earthquake (America, 1994), ChiChi Earthquake (Taiwan, 1999) and Kocaeli Earthquake (Turkey, 1999); the 80 FF ground motions records belongs to the previous strong seismic events, with the addition of Whittier Narrows Earthquake (America, 1987) and Kobe Earthquake (Japan, 1995). Table 1 reports the selected NF ground motions.

Based on the identification approach described in section 3, all the NF ground motions have been identified as pulse-like ground motions. Due to the limited space, only their energy index  $E_p$  is shown in Fig. 10.

Fig. 10. Energy index  $E_p$  for NF ground motions selected

### 4.3 Fragility analysis

As stated before, the main damage is expected to be in the pier, which is the most vulnerable element of the bridge with potential catastrophic consequences. Usually piers experience different degrees of damaging, from the cover spalling of concrete to the buckling of longitudinal reinforcement or bar fracture. In what follows these three damage levels have been assumed as Damage Measures. Berry and Eberhard (2003), developed empirical equations to estimate deformations at the above damage levels calibrated with a series of existing experimental tests from the UW-PEER reinforced concrete column performance database, which include the performance of over 400 columns. Concrete cover spalling represents the initial damage state that may cause a possible short-term loss of functionality along with a significant repair cost. Bar buckling and fracture represent instead damage states in which safety implications are particularly important, which may imply partial replacement and a longer term loss of functionality. Concrete cover spalling, bar buckling and bar fracture can be defined as a moderate, extensive and complete damage condition. A closed-form of the median value of the drift (mC) was proposed by Berry and Eberhard for damage estimation, which read:

$$\begin{aligned}
 \frac{\Delta_{sp}^{calc}}{L} (\%) &= 1.6 \left( 1 - \frac{P}{A_g f'_c} \right) \left( 1 + \frac{L}{10D_e} \right) && \text{Concrete cover spalling} \\
 \frac{\Delta_{bb}^{calc}}{L} (\%) &= 3.25 \left( 1 + k_e \rho_{eff} \frac{d_b}{D_e} \right) \left( 1 - \frac{P}{A_g f'_c} \right) \left( 1 + \frac{L}{10D_e} \right) && \text{Bar buckling} \\
 \frac{\Delta_{bf}^{calc}}{L} (\%) &= 3.25 \left( 1 + k_e \rho_{eff} \frac{d_b}{D_e} \right) \left( 1 - \frac{P}{A_g f'_c} \right) \left( 1 + \frac{L}{10D_e} \right) && \text{Bar fracture}
 \end{aligned} \tag{20}$$

where  $k_e = 40$ ,  $\rho_{eff} = 0.307$  volumetric transverse reinforcement ratio,  $f'_c$  concrete compressive strength,  $d_b$  diameter of the longitudinal reinforcement,  $D_e$  column depth,  $P$  axial load at the column base,  $A_g$  gross area of the cross-section and  $L$  distance from the column base to the point of contra flexure. An alternative representation of the damage condition in the pier is the plastic deformation at bottom section. The corresponding levels of damage, obtained in the pier, are for concrete cover spalling 1.37%, for buckling 4.25% and for fracture 8.96 %.

According to the HAZUS99 (1999), the damage indices represented the damage of bridge piers are defined as the ductility ratio. Using the case data, the damage indices are calculated and converted to the drift ratio. The results are 0.63% for slight damage, 1.31% for moderate damage, 4.31% for extensive damage and 12.3% for complete damage. Compared to the results of Berry and Eberhard method, the values of damage indices for moderate damage and extensive damage are close. The usefulness of this method is manifested. For the experimental results which are generally considered being more reliable, the results of Berry and Eberhard method for moderate, extensive and complete damage are defined as the main damage indices while the slight damage index of the HAZUS results is the supplement. The comprehensive damage index of the pier is listed in Table 3.

Table 3. Damage index for pier drift ratio

	Slight damage	Moderate damage	Extensive damage	Complete damage
Damage index (Drift ratio)	0.63%	1.37%	4.25%	8.96%

Concerning the aleatory uncertainties considered in fragility analysis, the dispersion of capacity fragility  $\square C$  is assumed equal to 0.3 based on the experimental data elaborated by Berry and Eberhard (2003). In Fig. 11 the seismic fragility curves with intensity measures  $S_a$  are shown; it is evident that the POE of any level of damage in the pier is larger for the NF pulse-like ground motions. In fact, in the considered range of the IMs, the maximum probability of exceeding bars buckling in the NF region is about 90%, while in FF region is about 60%; the probability of bars fracture is about 30% under NF pulse-like ground motions and only 5% in the FF region.

Fig. 11. Comparison of fragility curves of piers with the given IMs on longitude: (a) slight damage, (b) moderate damage, (c) extensive damage, and (d) complete damage

In contrast to aleatory uncertainties, which are essentially irreducible, the epistemic uncertainties generally can be reduced through additional knowledge provided at the expense of more comprehensive (and costly) data acquisition and analysis. Existing studies indicated that the dispersion of fragility in terms of epistemic uncertainties can be assumed as 0.2 (Ellingwood et al. 2009; Haleem et al. 2010).

With the point estimation and interval estimation method mentioned in section 2.4, the fragility curves for near-fault earthquakes considering both aleatory and epistemic have been developed. They are illustrated in Fig. 12. The epistemic uncertainties are labelled as EU. The bounds of the belief interval is assumed to 16% and 84%.

Considering the epistemic uncertainty discussed in Section 2.4, seismic fragility curves with point estimation and interval estimation have been developed. Fig. 12 depicts fragility curves for each limit state. For slight damage and moderate damage, the probability considering epistemic uncertainties is similar to the probability with only aleatory uncertainties, and the epistemic uncertainty can be neglected. But the probability with EU is always bigger than the probability without EU in the considered range of IM. So it is meaningful to consider the

epistemic uncertainty for fragility estimation when the bridges face to extreme events, which can in-duce the extensive damage and complete damage.

It is easy to see that the interval of probability estimation is increasing with the damage. A possible reason is that the epistemic uncertainties reduce the accuracy of probabilistic models for the heavy damage states.

Fig. 12. Point and interval estimate for near-fault earthquake fragility curves considering epistemic uncertainty: (a) slight damage, (b) moderate damage, (c) extensive damage, and (d) complete damage

#### 4.4 Probabilistic Resilience estimation

System and component level fragility curves have been shown in the previous section. Based on these data, the seismic resilience analysis of the selected case study has been performed following the method presented in Section 2.3. The bridge is assumed to be located in Los Angeles, California, USA, whose hazard curves, for a reference life of 100 years, has been provided by the the United States Geological Survey (USGS).

Considering the scarcity of statistical data concerning loss and post-earthquake recovery for bridges, in this work the loss estimation for highway bridges in California (ATC-13, 1985) has been used. In particular, the functionality recovery functions proposed by expertise-based surveys have been adapted for seismic resilience estimation. The selected recovery function is

specific for steel-concrete composite highway bridges, whose functionality is defined as the traffic capacity and the category is 25c.

Fig. 13. Functionality recovery profiles from ATC-13

The recovery profiles of the function are listed in tabular form and present the mean time required to recover specific percentage (30%, 60%, 100%) of normal functionality. For the present study, referring to the damage definition provided by ATC-13, the damage states 2 through 5 are assumed to be the corresponding damage states from slight to complete damage. The selected recovery function is presented in Fig.13.

According to ATC-13, the time horizon investigated for the functionality recovery function from is 303.6 days. Consequently, the time horizon of the expected functionality restoration is limited to maximum of 303.6 days by using Equation (7).

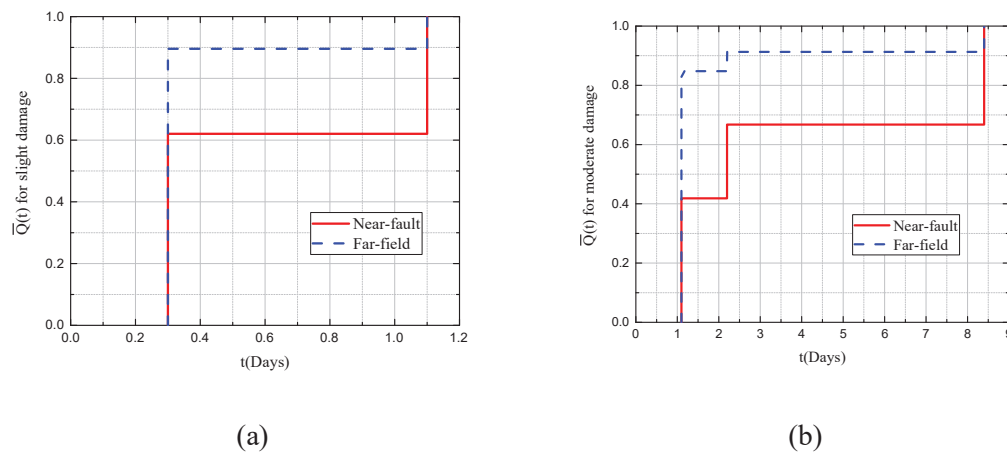

Fig. 14. Expected functionality recovery of bridge at different damage levels: (a) slight damage, (b)moderate damage, (c)extensive damage, and (d)complete damage

Fig. 14 illustrates the expected functionality recovery processes of the bridge for each damage state. Two recovery profiles are presented in the figures both for near-fault and far-field earthquakes. The expected functionality recovery of the whole bridge is instead shown in Fig. 15. Assuming that the total recovery time is constant and the initial damage is null, the obtained functionality paths appears rather different. It can be easily seen that the damage caused by

near-fault earthquakes is more hard to be recovered. In other words, the seismic resilience demand of the bridge struck by near-fault earthquakes is larger than resilience demands coming from far-field earthquakes.

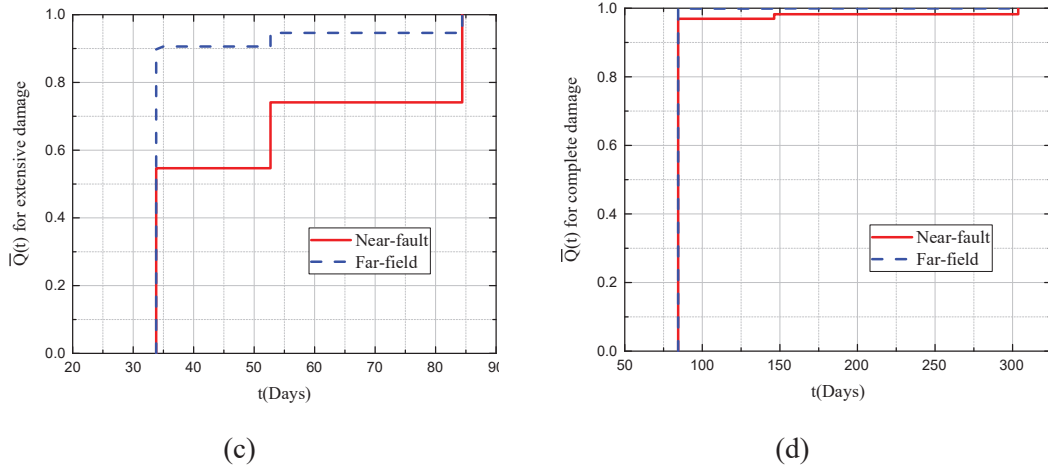

Fig. 14. Expected functionality recovery of bridge at different damage levels: (a) slight damage, (b) moderate damage, (c) extensive damage, and (d) complete damage

Fig. 15. Expected functionality recovery of whole bridge

Using the fragility curves with epistemic uncertainties (Fig. 16 and 17), the expected functionality recovery estimation can be developed also by using Equation (10). The interval estimation of recovery curves presents a variation tendency similar to fragility curves, which is more uncertain for higher damage. As shown in Fig. 15, it is easy to find that the interval estimation width is broaden for increasing recovery time. This is caused by the increasing of epistemic uncertainty with damage states and the variation of recovery service.

Fig.17. Interval estimation and point estimation of expected functionality recovery for whole bridge

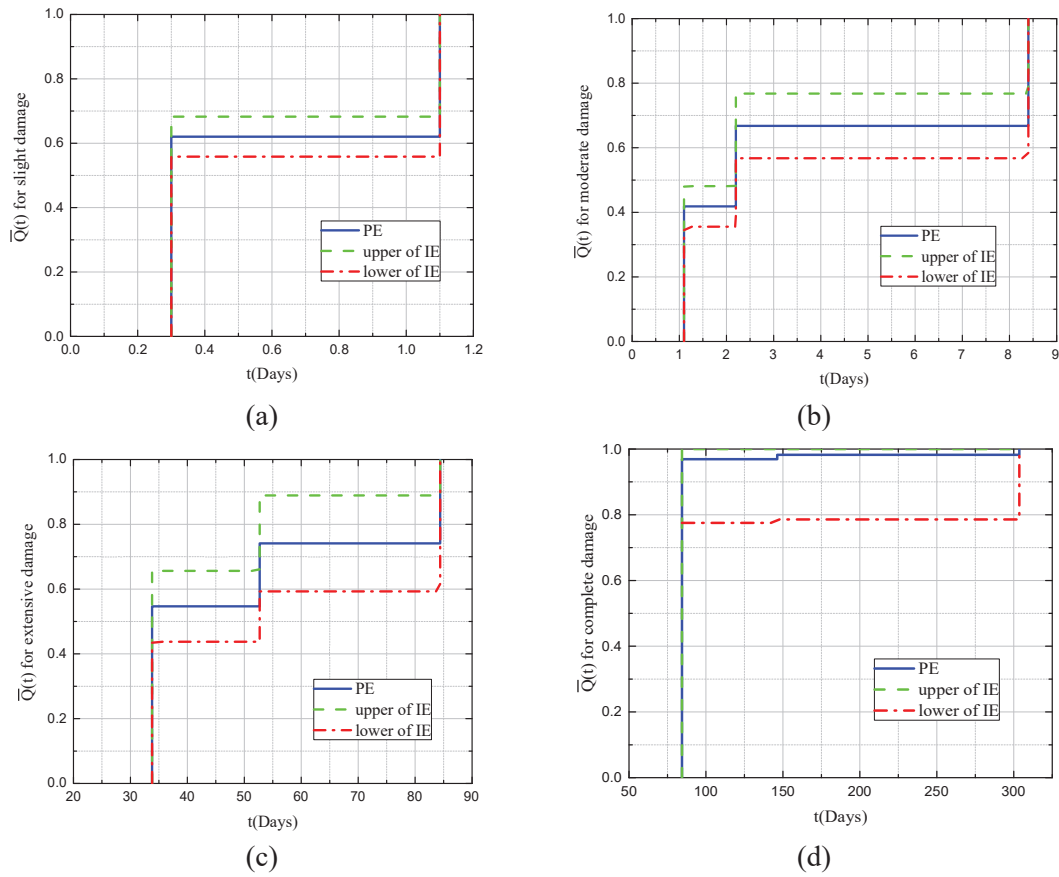

Fig. 16. Point estimation and interval estimation of expected functionality recovery at different damage levels: (a)slight damage, (b)moderate damage, (c)extensive damage, and (d)complete damage

The resilience of the bridge can be determined using Equation (9). The resilience index is shown in Table 4. It can be found that the resilience of the bridge struck by far-field earthquakes

(0.98) is larger than that under near-fault earthquakes (0.89). The horizon of resilience interval estimation for this type of bridges under the near-fault earthquakes ranges from 0.91 to 0.86.

Table 4. The expected resilience index of bridge

	Near-fault	Far-field
Expected resilience index	0.89	0.98
Upper of interval estimation	0.91	-
Lower of interval estimation	0.86	-

## 5 CONCLUSIONS

The probabilistic seismic resilience of steel concrete composite bridges with concrete cross beams is estimated by a simulation approach and the resilience demand after the near-fault earthquake events is quantified. The following conclusions are obtained:

1. The assessment process of seismic resilience is performed in a probabilistic way by using the seismic fragility analysis and considering both aleatory and epistemic uncertainties derived respectively from earthquakes and the structure.
2. It has been found that the uncertainties of the restoration path increase along the time and when more severe damage occurs.
3. The near-fault pulse-like earthquakes have significant effects on the seismic performance of the bridge. The result have shown that the estimation resilience of the bridge under NF earthquakes is about 10% less than FF earthquakes; the function restoration indicates that the bridge under NF earthquakes is more difficult to recover than that under FF earthquakes.
4. It has been demonstrated that the simplified approach proposed in this paper can be profitably used to approximately and easily estimate the seismic resilience of a steel concrete composite bridge. This suggests further developments devoted to the extension of the method for the calculation of the resilience of bridge network systems.

It has been found that the main barrier for the seismic resilience assessment is limited by the scarce number of studies investigating the functionality recovery functions. In this respect, current on-going research activities concerning this aspect will lead to better restoration process models, which it will increase the assessment accuracy..

### **Abstract**

*Existing R.C. bridge structures are generally subject to intense environmental attacks. Over time, environmental actions can trigger structural deterioration effects, the most common of which is the rebars corrosion. As steel reinforcement corrosion could reduce the capacity of R.C. members, the seismic safety of R.C. bridges could be compromised by these phenomena. In accordance with international guidelines, the initial assessment of bridges is carried out by identifying and grading defect-indices after a visual inspection of the structure. This study arises from the need to find a quantitative correlation between the grading scale adopted in the evaluation of defect-indices and the impact of corrosion effects on RC members capacity and safety, also evaluating the evolution over time of degradation. A practical simplified, whilst mechanical-based, analytical methodology for assessing the seismic safety starting from defect-index visual assessment of RC bridges subject to degradation corrosive attacks, is presented and applied to a case study RC bridge representative of the main characteristics of the viaducts of Italy. Different chloride damage scenarios related to defect-indices are considered for the piers of the case study bridge and the seismic safety of the structure is analytically evaluated. Two corrosion rate limit conditions are then considered to evaluate (upper and lower bound) effects on seismic safety over time. Finally, an estimate of the epistemic uncertainty due to the visual assessment of the damage is performed to obtain the structure collapse probability. The analytical results underline that the seismic safety is strongly influenced both by the location and the evolution of corrosion phenomena over time. By identifying the safety and collapse probability of the structures, the proposed methodology can be used as a decision-making support tool regarding the need for intervention with maintenance/restoration/retrofit solutions.*

## 1 INTRODUCTION

The structural-seismic safety assessment of existing reinforced concrete bridges is a long-standing key topic in civil engineer [1]. The Italian territory, characterized by medium-high seismicity, has a large stock of old RC bridge structures, typically prior to the introduction of seismic-resistant and durability principles and code provisions [2-4]. Deterioration phenomena may be triggered by aggressive environmental conditions for RC structures lacking adequate construction details. In these cases, corrosion of reinforcing rebars represents the most frequent and dangerous deterioration phenomenon. Once activated, corrosion can occur in a uniform or localized manner; uniform corrosion is caused by humid and carbon dioxide-rich environmental conditions; pitting corrosion instead activates due to the penetration of chloride ions in concrete, a frequent case for bridges due to the application of de-icing salts.

Corrosion of the steel reinforcement affects the mechanical properties of the materials, leading to reduction of the resistant section of the steel bars and of the reinforcement deformation capacity, cracking of cover concrete, and deterioration of the bond strength. In recent decades, considerable efforts have been devoted to understanding the mechanical behavior of corroded R.C. members. In Rodriguez et al. 1997 [5], Castel et al. 2000 [6], Meda et al. 2014 [7] experimental tests were carried out to evaluate flexural, shear and cyclic behavior. The effects on material properties such as stress-strain and/or bond strength laws were identified in Alonso et al. 1996 [8], Almusallam et al. 2001 [9], Apostolopoulos et al. 2008 [10], Imperatore et al. 2017 [11], FIB Model Code 2020 [12]. The reinforcing bars corrosion phenomenon is characterized by two phases [13]: the initiation phase, when atmospheric agents penetrate the concrete until the reinforcement depassivation, and the propagation phase when the impact on materials further evolve over time. Since the seismic performance of bridge structures is highly dependent on the mechanical behavior of its elements, thus on the state of decay, the assessment of seismic structural safety of existing structures and infrastructures should take into account the quantitative evaluation of capacity reduction and its impact on performance/safety due to rebars corrosion.

Given the key strategic role of bridge structures within a country's road network, and the potentially substantial socio-economic costs associated with demolition-reconstruction interventions, several national and international guidelines on the evaluation of existing reinforced concrete bridges have been issued in recent years [14,15]. The common goal is to develop practical and reliable bridge-state assessment procedure and define appropriate maintenance-retrofit solutions for degraded and unsafe structures. Some of these guidelines (e.g., [14]), provide for a multilevel (tiers) approach based on the identification of defect indices following a

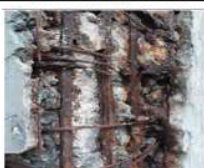

Visual Inspection	Defect	Severity (G)	Extention (k1)	Intensity (k2)	Total Score
	Umidity	x	x	x	G * k1 * k2
	Concrete Deterioration	x	x	x	
	Cracking	x	x	x	
	Cover Spalling	x	x	x	
	Stirrups Corrosion	x	x	x	
	Rebars Corrosion	x	x	x	
Relative Defect Coefficient				$\sum_i G_i * k1_i * k2_i$	

Figure 1: Example of Defect Indices Datasheet

visual inspection of the structure: for each area of the bridge the defects are identified, and through "qualitative scores" the severity and extent of the defects are graded. Figure 1 shows an example on how these approaches work. The Relative Defect Coefficient (DS) is calculated from the weighted sum of the individual defects (G) multiplied by the intensity ( $k_1$ ) and extension ( $k_2$ ) coefficients. Depending on the overall scoring (DS), the codes provide procedures that may highlight the need for more in-depth investigations, aimed at verifying the effective structural capacity, or the possibility of carrying out only maintenance interventions or proceeding with the downgrading of the bridge.

In the authors' opinion, such approach, based on visual inspections, could and should be further developed using mechanical-based methodologies in order to quantitatively evaluate the potential capacity-reduction of RC structural members and, therefore, of the structures static and seismic safety.

The aim of this work is to develop and integrate a quantitative mechanical-based assessment of RC members to the visual inspection and defect indices qualitative "scoring" approach in order to suggest a methodology for structural and seismic safety assessment of deteriorated RC bridges. To achieve this goal, a practical analytical methodology [16,17,18,19,20], whilst mechanical-based, referred to as SLaMA (Simple Lateral Mechanism Analysis) is further extended to for the evaluation of the seismic performance/safety evaluation of existing bridges, specifically including considerations on the capacity assessment of corroded RC structural members. In this work, the seismic safety of a case study reinforced concrete bridge, representing an archetype of widespread bridge typologies in Italy, affected by corrosion phenomena, is evaluated. Three different degradation scenarios are considered: corrosion intensity in terms of percentage mass loss is chosen consistently with three different defect indices, defined according to [14], thus integrating a quantitative measure to the visual inspection approach. Corrosion effects on members capacity reduction are analytically calculated as reported in [11,21,22]. The global seismic capacity of the bridge is determined and therefore the safety index defined in [14] is calculated. Considering different corrosion propagation models [23,24,25,26], upper and lower bounds for corrosion rates are adopted, and the seismic safety reduction over time is assessed. The uncertainty related to the location and extent of degradation is evaluated, and finally, using a simplified probabilistic approach [27] the fragility curves associated to the bridge collapse probability are calculated as a function of the peak ground acceleration for each degradation scenario.

## 2 SLAMA-BRIDGE METHODOLOGY INCLUDING DETERIORATION EFFECTS

The proposed procedure, schematically shown in the flow-chart of Figure 2, consists of the simplified seismic assessment of existing RC bridges based on the SLaMA approach for bridges [16,17,18,19], integrated with the evaluation of element capacity reduction evaluation due to corrosion of the reinforcement bars. As a first step, the seismic capacity of the pier is calculated determining the force-displacement curve. In this phase, it is crucial to correctly identify the 'critical section' where the plastic hinge and potential associated energy dissipation is expected to occur and develop. Generally, for bridges piers the plastic hinge region is expected to be located as the base, given their cantilever scheme; however, in case of localized environmental corrosive attack, the structural deterioration can modify the structural nonlinear behavior, and consequently, the critical sections can be relocated [28].

Therefore, it is important to support such estimation on the specifically planned visual inspections of the degradation. As part of the members capacity evaluation, the interaction between flexure and shear mechanisms is taken into account by comparing the force-displacement curve and the degrading-shear capacity curve calculated according to [29].

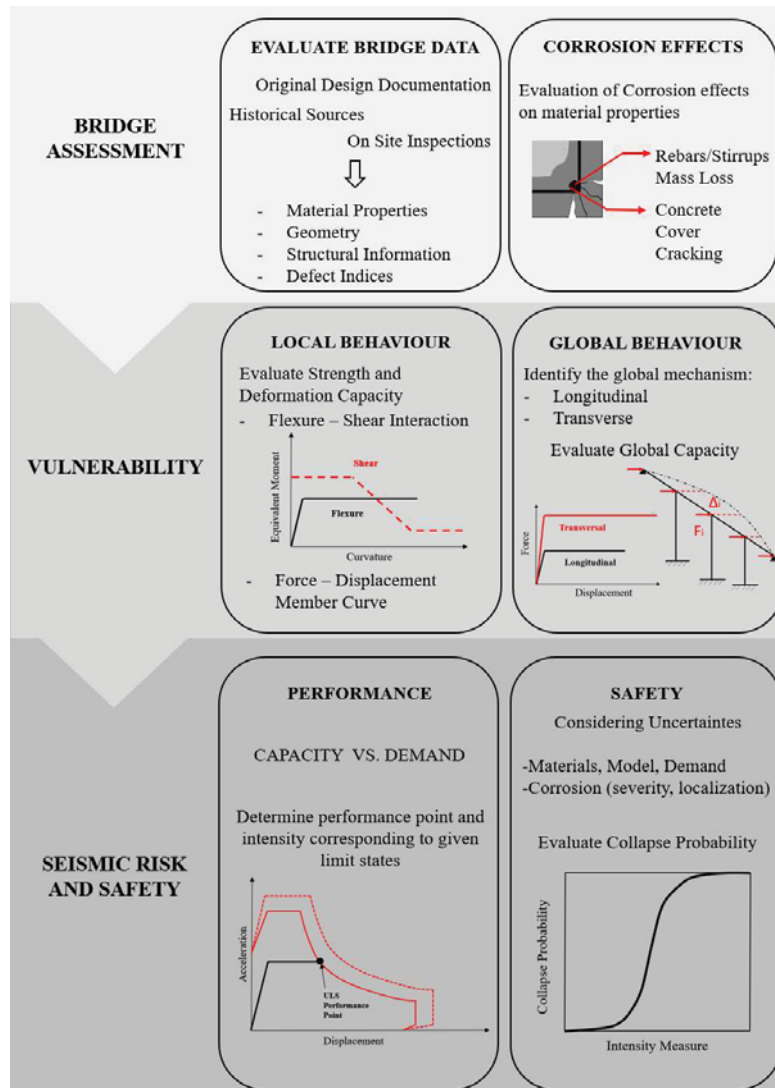

Figure 2: Methodology Flow Chart

In this paper, the evaluation of the plastic hinge length is calculated as the average value of the results related to different formulations available in the literature [30,31,32]. In a section analysis (or fiber numerical model) approach, the corrosion effect is taken into account by reducing the mechanical properties of the reinforcements as reported in [11] and by reducing the concrete cover compressive strength to consider the cracking induced by oxides expansion [33,34]. The overall seismic capacity of the bridge is evaluated separately for the longitudinal and transverse directions. The relationship between the local and global capacity is closely related to the static scheme of the bridge. The most common schemes for existing reinforced concrete bridges are continuous beam and supported beam ones. As reported in [35], in case of supported beams, and in the absence of seismic restraints, each pier behaves independently therefore, in a simplified way, the performance of the bridge is governed by the performance of the weakest (performance-wise) pier, both in longitudinal and transverse direction. On the other hand, in the case of continuous beam scheme: in the longitudinal direction, same top displacement can be assumed for all piers and the overall capacity is obtained by adding in parallel the individual

capacities of each pier; in the transverse direction, following a displacement approach presented in [36], the global capacity curve is obtained by adding the singles piers capacity in proportion to the piers effective displacement identified for the principal vibration mode of the structure. The global displacement instead is determined by referring to an equivalent SDOF. The seismic safety is measured through the safety index  $\zeta_E$  (also referred to as IS-V and %NBS in the ITA2017 and NZSEE2017 guidelines, respectively) [14, 16, 29], or Capacity/Demand ratio, obtained by comparing the bridge capacity curve with the ADRS seismic demand spectrum SLV limit state [29].

One of the objectives of this paper is the further extension of the analytical assessment methodology to account for the potential reduction of safety over time. To achieve this scope, an extensive literature review on research on the corrosion rate models available in the literature has been carried out, both for the carbonation and for the chlorides attack phenomenon. Since pitting corrosion due to chloride attack is characterized by a higher rate (Figure 3), in this work this typology is considered for the deterioration scenarios applied to the structure.

Figure 3: Corrosion rate models. a) Carbonation. b) Chlorides attack.

In the Defect Indices Approach through visual inspections, no explicit empirical or theoretical relationships are associated to the determination of the so called “extension” and “intensity” coefficients, and, at this stage, there are no quantitative correlation between the grading scale and the actual mechanical material properties reduction, making a structural mechanical assessment that takes into account deterioration phenomena not applicable.

To overcome these issues, a probabilistic approach is adopted in this work: the probability of the structure to overcome a certain damage level is determined as a function of the seismic intensity. The fragility curves can be calculated through analytical or empirical methods. In [27] most of the analytical methods adopted for buildings are presented. In [37] empirical methods are proposed for the calculation of the fragility curves according to the considered structure.

For the sake of simplicity and in the absence of more detailed data, in the simplified collapse probability assessment procedure herein proposed for a corroded reinforced concrete bridge structure, variations in the main factors affecting the corroded member capacity are considered, in particular: the location of the critical section, the amount of lost mass and the number of bars involved. Extensive analyses have been carried out varying both parameters.

In this way both corrosion location and intensity uncertainty related to the assumed deterioration scenarios are accounted and then combined, as recommended in [28], through SRSS rule with the epistemic (model and material characteristics) and aleatoric (seismic demand) uncertainties  $\beta$  value of 0.6 suggested in [37].

### 3 CASE STUDY BRIDGE

#### 3.1 Geometric and mechanical characteristics

The case study Bridge is an archetype representative of typical characteristics of a large number of R.C. bridges in the Italian territory (Figure 4). The geometry, material properties and static scheme of the bridge were selected through the analysis of a database of the Italian bridges in central Italy [20]. The database shows a strong prevalence of supported beam scheme, therefore herein selected for the case study. The bridge consists of four 30 m spans. Deck beams consist of I-shape prestressed reinforced concrete with prestressed 7-wire strands with straight longitudinal profile. The Piers have hollow polygonal section. Table 1 reports the key geometric characteristics of piers. The material mechanical properties (Table 2) have been selected as average values of the concrete cubic compressive strength and of the reinforcement yield strength values available in the database. In this regard, it is worth noting that material properties design values are obtained by reducing the mean values by partial safety factors and knowledge factor according to the Italian Code Provisions NTC2018 and associated Commentary 2019 for existing Structures and Infrastructures [14,29].

Figure 4: Archetype example for Italian Territory bridges

Pier Section	Lenght	$A_{conc}$	$\Phi_{long}$	$\rho_{long}$	$\Phi_t$	s

26.80	29.57	0.2	0.35	375.00	210.00	0.18	6.75

Table 2: Case study piers material properties

As regards the seismic demand, conditions of high seismicity were considered. Reference is made to the L'Aquila site, representative of the seismology of central Apennine Italy. A nominal life  $V_N = 100$  years and an Importance Level IV (Important strategic functions structures) [29] are considered in order to account for the strategic function of the bridge structure. In Table 3 the main parameter of the elastic acceleration response spectrum are presented for the limit states of (Fully) Operational (SLO), Damage Control (SLD), Life Safety (SLV) and Collapse Prevention (SLC).

$P_{VR}$	$T_R$	LIMIT STATE	$a_g$	$F_0$	$T^*_C$
[-]	[years]	[-]	[g]	[-]	[s]
81%	120	SLO	0.15	2.3	0.30
63%	201	SLD	0.19	2.31	0.32
10%	1898	SLV	0.41	2.44	0.38
5%	2475	SLC	0.45	2.46	0.38

Table 3: Response spectrum parameters

Three different degradation scenarios are applied to the case study bridge in order to evaluate the potential losses in terms of seismic safety due to the corrosion effects. Each scenario, representative of a specific degradation level, is associated to the “Relative Defect Coefficient” evaluated according to the qualitative defect sheets of the Italian guidelines for the evaluation of existing bridges. In Figure 5 visual examples for assumed degradation scenarios are given.

Figure 5: Examples of degradation scenarios: a) Low degradation – Scenario 1. b) Medium degradation – Scenario 2. c) High degradation – Scenario 3.

<b>Scenario 1 - Low Degradation</b>				
Defect	Severity	Extention	Intensity	Total Score
Umidity	4.00	0.50	1.00	2.00
Concrete Deterioration	2.00	0.50	1.00	1.00
Cracking	2.00	1.00	0.20	0.40
Rebars Corrosion	5.00	0.20	0.20	0.20
Relative Defect Coefficient				3.60
<b>Scenario 2 - Medium Degradation</b>				
Defect	Severity	Extention	Intensity	Total Score
Umidity	4.00	0.50	1.00	2.00
Concrete Deterioration	2.00	0.50	1.00	1.00
Cracking	2.00	1.00	1.00	2.00
Cover Spalling	2.00	0.20	1.00	0.40
Stirrups Corrosion	3.00	0.50	0.50	0.75
Rebars Corrosion	5.00	0.20	0.50	1.25
Relative Defect Coefficient				7.40
<b>Scenario 3 - High Degradation</b>				
Defect	Severity	Extention	Intensity	Total Score
Umidity	4.00	0.50	1.00	2.00
Concrete Deterioration	2.00	0.50	1.00	2.00
Cracking	2.00	1.00	1.00	2.00
Cover Spalling	2.00	0.20	1.00	2.00
Stirrups Corrosion	3.00	0.50	0.50	1.50
Rebars Corrosion	5.00	0.20	0.50	1.25
Relative Defect Coefficient				10.75

Table 4: Degradation scenarios parameters considered for the case study

In Table 4 the degradation parameters assumed for each scenario are presented. For the Scenario 1, low degradation conditions are considered: it is assumed that corrosive agents have broken the protective film of the bars but the corrosion of the latter has just begun ( $M_{\text{loss}} = 5\%$ ), the most obvious defect being the extensive deterioration of the concrete with capillary cracking. In Scenario 1, the extent of the degradation is considered localized. The position of deterioration is parametrically shifted to assess the influence of the location of the damage on the capacity of the structure. For the Scenario 2, medium degradation conditions are considered with rebars corrosion ( $M_{\text{loss}} = 15\%$ ) and partial detachment of the concrete cover. Also for Scenario 2 the extent of the deterioration is assumed localized. For the Scenario 3, severe and limit conditions are considered: rebars corrosion is high ( $M_{\text{loss}} = 25\%$ ) and the stirrups are no longer considered resistant, the concrete cover has spalled and the extent of the damage affects a large part of the pier. In Table 5 the corrosion consequences on material properties are presented for each scenario, the reinforcement mass loss values ( $M_{\text{loss}}$ ) were chosen consistently with values found in the literature for chlorides corrosion [11, 35].

	Steel					Concrete	
	$M_{loss}$	$\varepsilon_{sy}$	$\varepsilon_{su}$	$f_{ym}$	$f_{um}$	$w$	$f_{c,rid}$
	[-]	[-]	[-]	[Mpa]	[Mpa]	[mm]	[Mpa]
Scenario 1	5%	0.20%	5.13%	337.57	489.67	0.12	26.37
Scenario 2	15%	0.12%	2.97%	260.27	389.00	0.82	24.21
Scenario 3	25%	0.09%	1.72%	186.11	288.33	4.09	21.12

Table 5: Corrosion consequences on material properties

Given the high uncertainty of the corrosion rate, an upper and a lower bound were identified through the study of predictive models available in the literature and adopted to evaluate the reinforcement mass losses,  $M_{loss}$  for the case study bridge over a period of 15 years. The limit values of the corrosion rates together with the consequent  $M_{loss}$  values assumed over time are shown in Figure 6.

Figure 6: Corrosion intensity evolution for each scenario: a) Lower bound corrosion rate. b) Upper bound corrosion rate

### 3.2 Safety reduction and risk assessment results

The models described above for the strength and ductility losses for structural members subject to corrosion were applied to the structure for the three deterioration scenarios. Figure 7 shows the moment-curvature curve for the weakest bridge pier for the non-corroded case and each corrosion scenario considered. It can be noted that as the degradation increases, a marked loss of element ductility is observed. This effect is mainly due to the reduction in terms of steel ultimate deformation capacity.

Then the bridge seismic capacity for each scenario was calculated. In Figure 8 the global capacity curves and expected performance within a ADRS (Acceleration Displacement Response Spectrum) domain are presented for the longitudinal direction. Worth noting that, as the seismic safety in the transverse direction did not present significant problems for any scenario, albeit with a reduction in vulnerability, the results have been herein omitted. As it can be observed, in the longitudinal direction the seismic safety check is no longer satisfied for all scenarios. The safety index reduces from  $\zeta_e=1.15$  for the non-corroded case to a  $\zeta_e=0.98$ , 0.71 and 0.61, for scenario 1, 2 and 3.

Figure 7: Moment-curvature relationship for the base section of bridge piers

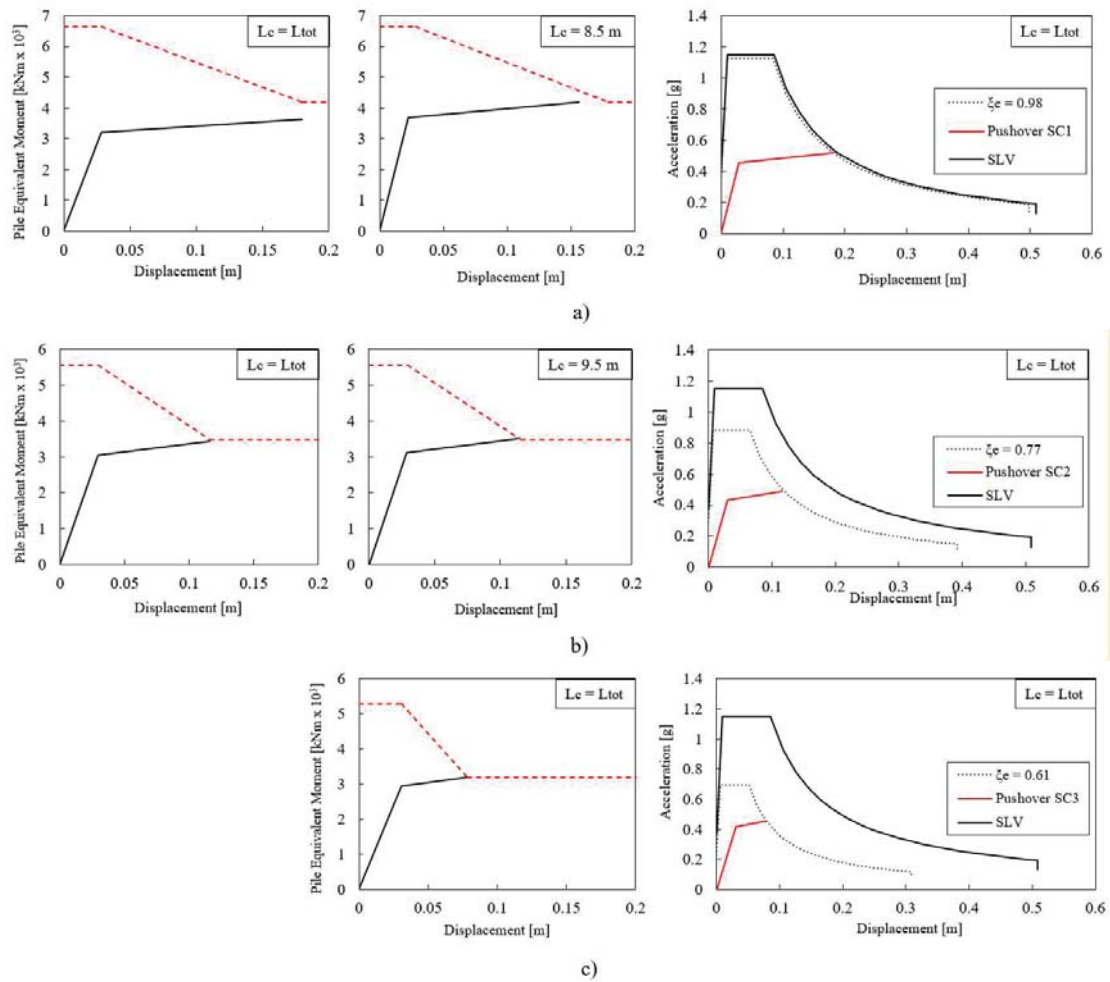

Figure 8: Capacity curves and safety index evaluation for the case study bridge. a) scenario 1. b) scenario 2. c) scenario 3.

Considering the upper and lower bound corrosion rate values previously described, the decay of the Safety Risk index over time is evaluated and shown in Figure 9. For the case study, a maximum percentage loss of seismic safety in 15 years of about 47% for scenario 3 is assessed. Reduction due to the upper bound corrosion rate in 15 years is about 15%, while for the lower bound is about 2.5% highlighting the extreme importance of this parameter characterized by high uncertainty.

In order to calculate the collapse probability of piers, variations in the intensity (3-30%  $M_{loss}$ ), in the number of corroded bars, in the critical damaged section location (base section, 0.25L, 0.5L) are considered. Altogether a sample of 186 performance data of the structure referred to the achievement of the ultimate displacement of the pile is obtained. The reference parameter is the PGA, peak ground acceleration, associated with a given damage state. The damage states considered are the displacement limits reported in the study in [39]. For the Collapse Prevention limit state the displacement limit considered is the ultimate one. The values obtained for the corrosion localization and damage uncertainties and the combination of the two with the epistemic and aleatoric uncertainties are reported in Table 6.

Figure 9: Safety factor decay over time due to corrosion development

	PGA	$\beta_{\text{model+materials+demand}}$	$\beta_{\text{localization}}$	$\beta_{\text{damage}}$	$\beta_{\text{localization+damage}}$	$\beta_{\text{total}}$
	[g]	[-]	[-]	[-]	[-]	[-]
Sound	0.43	0.6	-	-	-	0.6
Scenario 1	0.4	0.6	0.17	0.16	0.24	0.65
Scenario 2	0.35	0.6	0.17	0.16	0.24	0.65
Scenario 3	0.31	0.6	0.17	0.16	0.24	0.65

Table 6: Main parameters for fragility curves calculation

The collapse probability curves were then calculated for the non-corroded bridge and each scenario considered. The results are reported in Figure 10. As the severity of the deterioration increases, the fragility curve shifts to the left. This indicates that, as expected, as the damage from deterioration increases, there is a greater probability of collapse for a given PGA (seismic intensity).

Figure 10: Collapse probability - Pier

#### 4 CONCLUSIONS

In this work, a practical methodology for the seismic safety assessment of reinforced concrete bridges subject to corrosion phenomena was presented. Furthermore, considering different corrosion propagation models, seismic safety losses were also evaluated over time. The methodology was applied to a case study bridge (archetype), representative of the most typical technology and structural scheme adopted in the Central Italy territory. Finally, considering the epistemic and aleatoric uncertainties related to the materials, to the model, to the seismic demand, and to the corrosion intensity and localization starting from a defect index, the methodology allows to calculate the collapse probability curves, considering the ultimate displacement of the piers as Engineer Demand Parameter and the PGA taken as Intensity Measure.

The assessment results of the case study show that for bridges with supported beam static scheme the sensitivity to corrosion phenomena may significantly undermine the structure seismic safety. For the most severe deterioration scenario, results in terms of safety factor and fragility curve show the need for retrofit intervention to recover the initial safety level. Results obtained for the mild and medium intensity scenarios, on the other hand, do not seem to cause immediate and significant reductions in safety. Yet the study of the evolution of corrosive phenomena over time shows that, in the case of high corrosion rates, safety may be compromised within a few years. For these cases it should also be considered that time can cause the deterioration to evolve not only in intensity but also in extension, thus potentially moving in a short time into a more severe deterioration scenario. In these cases, therefore, although structural restoration interventions might not be urgent, continuous monitoring and appropriate maintenance plans including preventive “light” restoration interventions might be critical to preserve the integrity and safety of the bridge in the long-term.

The analyses carried out show a significant loss of capacity in the case of localization of a weak section along the height of the pier rather than at the base.

The methodology presented, both for its simplicity and its effectiveness can represent a useful support tool integrating the visual inspection approach for assessing the corrosion effects on the R.C. bridge piers and therefore evaluating the overall structure seismic capacity. It can, therefore, represents a valuable decision support tool in terms of retrofit/restoration/maintenance

priorities related to the seismic performance of the structure. Further improvement and refinement of the methodology are needed and are under developments, to include further sources of material deterioration as well as local and global failure mechanisms.

Yet, in the authors' opinion, the high uncertainty associated with the corrosion phenomena, both in terms of mechanical consequences and in evolution over time, remains the main issue in the evaluation of seismic capacity. In this regard, the fragility curves evaluated through the proposed methodology can somehow account for this lack of current knowledge in the form of aleatoric and epistemic uncertainties. In any case, an adequate integration of the various approaches, e.g. visual inspection, theoretical quantitative evaluation and mechanical on-site testing, within a unified framework and assessment procedure can lead to a robust hybrid procedure for a more reliable estimation and control of the static (and seismic) performance and safety of bridge structures.

### Abstract

*CIPCast DSS, is a complex yet user-friendly and interoperable Decision Support System platform supporting the risk assessment and the real-time 24/7 operational monitoring of interdependent distributed critical infrastructures. CIPCast DSS is the reference platform for EISAC.it, the Italian node of the European Infrastructure Simulation and Analysis Centre. This paper presents the customization of CIPCast DSS to support the management of road networks in the aftermaths of an earthquake event, providing information on the damage and residual functionality of viaducts and bridges and the estimations of the earthquake-induced impacts in the surrounding natural and built environments. CIPCast DSS allows to support the identification of the areas and sections of the road networks that have been exposed to the ground shaking, and to estimate, in a simplified way, earthquake-induced damages for the road network components. Towards that fragility curves, numerical model analysis and data from Structural Health Monitoring (SHM) systems and sensors are used. The paper proposes physical damage indicators for bridges to be included in CIPCast DSS and the possible layout of SHM sensors to support their detection.*

## 1 INTRODUCTION

In Italy the road network is still the main transportation means for both people and goods; every year, about 8 millions vehicle and nearly 2 billion tons of goods (87% of the total Italian traded goods) travel along the Italian highway network [1]. Some sections of the Italian highway network (such as A24 and A25) are crucial for emergency operation in the event of crises and disasters. The business-as-usual maintenance and post-event effective management of highway networks are therefore fundamental to guarantee the well-being of the served communities, to support the logistic and the functionality of the economic systems and to guarantee a rapid and effective reconstruction and recovery after critical events.

Italy has more than 50 thousand kilometres of road and counts more than 2 thousand kilometres of artworks, more than half built before 1980 [1] when seismic prescriptions were almost inexistent. A meticulous assessment of the structural integrity of these structures is therefore imperative together with an evaluation of the resilience of the road network.

Particular attention should be paid to the vulnerability assessment of bridges and viaducts, considering the traffic load demand which they are subjected to (that might be higher than the one they were designed for), and the possible presence of pre-existing damage induced by environmental degradation and/or by critical event, such as earthquakes and floods.

Towards that the “*Linee Guida ponti*” [2] i.e. “*Guidelines for Risk Classification, Risk Management, Safety Evaluation and Monitoring of Existing Bridges*” released by MIT, Italian Ministry for Infrastructure and Transports, have defined a detailed operative framework for the classification and the structural safety assessment of the Italian bridges.

The idea presented in this paper is to embed the aforementioned institutional framework for the risk assessment of bridges in *CIPCast (Critical Infrastructure Protection risk analysis and foreCAST) Decision Support Systems (DSS)*, referred hereafter as *CIPCast DSS*, where scenario analysis can be performed considering also interdependencies and cascading effects, to support risk assessment and resilience enhancement of the whole road network. After a brief overview on worldwide initiatives to promote the resilience of highways and road networks and a non-exhaustive literature review on related DSS, the Italian platform *CIPCast DSS* is introduced and described as a potential tool for the risk analysis, the real-time monitoring, the business as usual as well as emergency management of Italian highway networks. In particular, the possible use of *CIPCast DSS* to support the post-earthquake management of highway networks is showcased in this paper, to provide to the control rooms and to the highway managers information on the earthquake-induced damage and residual functionality of bridges of the highway network as a whole, and on the possible impacts on the surrounding natural and built environments. In particular, the actual state and residual functionality of bridges is estimated in *CIPCast DSS* through Key Performance Indicators KPIs by combining the results obtained from empirical methods, numerical models, and, when available, performance indicators assessed from the data collected by SHM systems [3, 4].

## 2 OVERVIEW ON INITIATIVES AND TOOLS TO SUPPORT THE RESILIENCE OF HIGHWAY NETWORKS

The resilience and risk management of Critical Infrastructures (CIs), including highway networks, has been the subject of several ventures at national government level worldwide in the last decades.

In 2006, the U.S. Department of Homeland Security published the National Infrastructure Protection Plan (NIPP), subsequently revised in 2009 and in 2013, to outline how private sector parties and government departments should operate and interact to evaluate the

security, to ensure the resilience and to manage the risk of CIs. The main purposes of the NIPP are the identification of threats and hazards that might affect CIs, the reduction of CIs vulnerabilities and the development of strategies for mitigating the potential consequences induced by critical events. Industrial Control Systems (ICS), new Operational Technology (OT), as well as Intelligent Transport Systems (ITS) and Road Network Operations (RNO) have been introduced in order to reach these goals.

In 2011, following Fukushima natural and nuclear disaster (March 11<sup>th</sup>, 2011), Japan developed a program to promote the resilience of CIs (including energy, water and transportation infrastructures) to critical events, investing on the program approximately 210 billion dollars [5]. In 2018, Japan approved the *Fundamental Plan for National Resilience* defining the principles that governs the resilience of CI aiming to prevent loss of human life, to avoid the dysfunctionality of administrative and economic systems, to reduce physical damages on structures, infrastructures and goods and to ensure a rapid and effective recovery after critical events.

In 2015, the Australian government released the *Critical Infrastructure Resilience Strategy* to ensure the continued operation of CI in the face of different possible hazards; the aim being to support CI owners and operators to be efficient in the management of both foreseeable and unforeseeable risks.

In Europe, in 2018, the white paper “*Resilience Management Guidelines for Critical Infrastructures*”<sup>1</sup> was outlined by combining the outcomes of 5 Horizon 2020 projects<sup>2</sup> the white paper promotes the implementation of an *European Resilience Management Guideline for Infrastructures*.

As far as DSS tools are concerned, among several existing valid prototypes and operational tools, two have been selected for a brief presentation in this section as they have a good fit for purpose as far as the aforementioned CI resilience initiatives and policy frameworks are concerned, namely: REDARS<sup>TM</sup> and CIPCast DSS.

REDARS<sup>TM</sup> 2, Risks from Earthquake Damage to Roadway Systems [6] is a public-domain software promoted and financially supported in the U.S.A. by the Federal Highway Administration (FHWA) that, since 1993, has been sponsoring a Seismic Research Program.

REDARS<sup>TM</sup> 2 can support the assessment of seismic-induced hazards including ground motion, liquefaction, and surface fault rupture and, by considering the vulnerability of the highway assets, can support the estimation of earthquake-induced damages for different components of the highway network, for both simulated and real events.

After the assessment of earthquake-induced physical damage on the road network, REDARS<sup>TM</sup> 2 can be used for assessing the post-disaster traffic states and to evaluate their influence on traffic flows aiming to estimate the increased travel-time along key life-line routes and the resulting economic losses and impacts on the served community.

Simulated events can be run in REDARS<sup>TM</sup> 2 for planning purposes to estimate the effectiveness of various seismic retrofitting options and strategies towards the mitigation of the seismic risk for the highway network.

In case of real event REDARS<sup>TM</sup> 2 can support network managers to conduct an informed and aware decision-making process towards an effective emergency management [6] and to identify the needed remedial actions, their cost and benefits.

<sup>2</sup> H2020 DRS-07-2014 Projects i.e.: DARWIN (<https://h2020darwin.eu/>), IMPROVER (<http://improverproject.eu/>), RESILIENS (<http://resiliens.eu/>), RESOLUTE (<http://resolute-eu.org/>) and SMR (<http://smr-project.eu/home/>);

CIPCast DSS is a WEBGIS-based software developed as part of the EU-funded FP7 project Critical Infrastructures Preparedness and Resilience Research Network, CIPRNet [7] for the real-time and operational (24/7) monitoring and risk analysis of built and natural environments, with special focus on the analysis of interdependent critical infrastructures such as electric power, water, telecommunication, road networks and strategic buildings.

CIPCast DSS is the main tool used by EISAC, the European Infrastructure Simulation and Analysis Centre, a European-wide network of national centres aiming to support the protection and resilience enhancement of Critical Infrastructures; the Italian EISAC center, namely<sup>3</sup> EISAC.it, already actively collaborating with providers of essential services, asset managers and operators of Cis, aims to collaborate with the Italian Department of Civil Protection (DPC), to support scenario and risk analysis for the protection and resilience enhancement of CIs.

In the following paragraphs, the functionalities of CIPCast DSS are briefly presented and discussed in relation to its possible use for supporting the emergency management of highway networks in the aftermaths of earthquake events and for risk mitigation purposes.

### 3 CIPCAST DSS FOR THE EFFECTIVE POST-EARTHQUAKE MANAGEMENT OF ROAD NETWORKS

CIPCast DSS could be applied in the management of highway networks, particularly in the decision-making process after an earthquake event [8]. The idea is to provide to operators and managers of the highway networks a tool, connected and interfaced with other tools, and deployed sensors (Figure 1), to be used both for the effective management of road networks in the aftermath of emergencies induced by natural events, including earthquakes. The focus of this paper is on the parameters used by CIPCast DSS to provide information to the asset managers on the safety and residual functionality of viaducts, and bridges in the aftermath of an earthquake event. A brief overview of how CIPcast DSS works, and which relevant databases are included in CIPCast geodatabases is provided here; a more exhaustive overview on the functions included in the platform can be found in [7], [8].

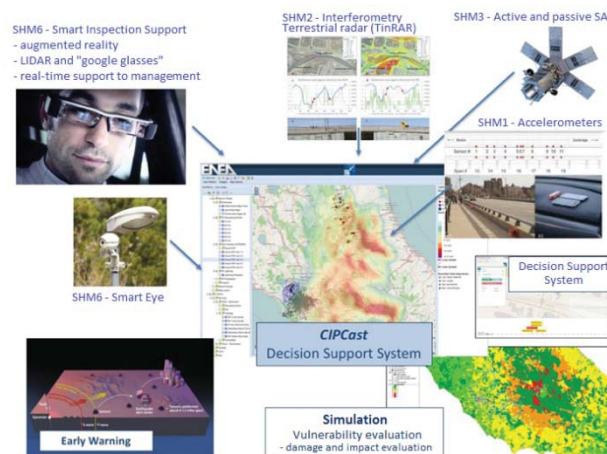

Figure 1: CIPCast DSS and possible connected tools and applications.

<sup>3</sup> EISAC.it (<http://www.eisac.it/>) was established in 2018 thanks to a collaboration agreement between ENEA, the Italian Agency for New Technologies, Energy and Sustainable Economic Development (<https://www.enea.it/en>) and INGV, the National Institute of Geophysics and Volcanology (<http://www.ingv.it/en/>).

CIPCast GeoDatabases, referred hereafter as CIPCast DBs allow the storing and management of large quantities of geospatial data obtained through GIS processing or from external sources including, among others, Open Data, field sensor data, third party or distributed repositories. The data can be stored locally or in different remote servers, accessible through services compliant with the Open Geospatial Consortium (OGC) standards. As far as the seismic assessment and management of the road networks is concerned CIPCast DBs include data for the assessment of both the seismic ground motion and seismic induced-hazard and for the characterisation of the seismic vulnerability of critical components such as bridges, viaducts tunnels and embankments. CIPCast DBs for the seismic hazard characterisation include among others: microzonation, faults location, surface faulting, liquefaction potential, earthquakes historical parametric catalogue; landslide and rock-fall hazard maps from past event and from satellite data SAR (Synthetic Aperture Radar) can be used (Figure 2).

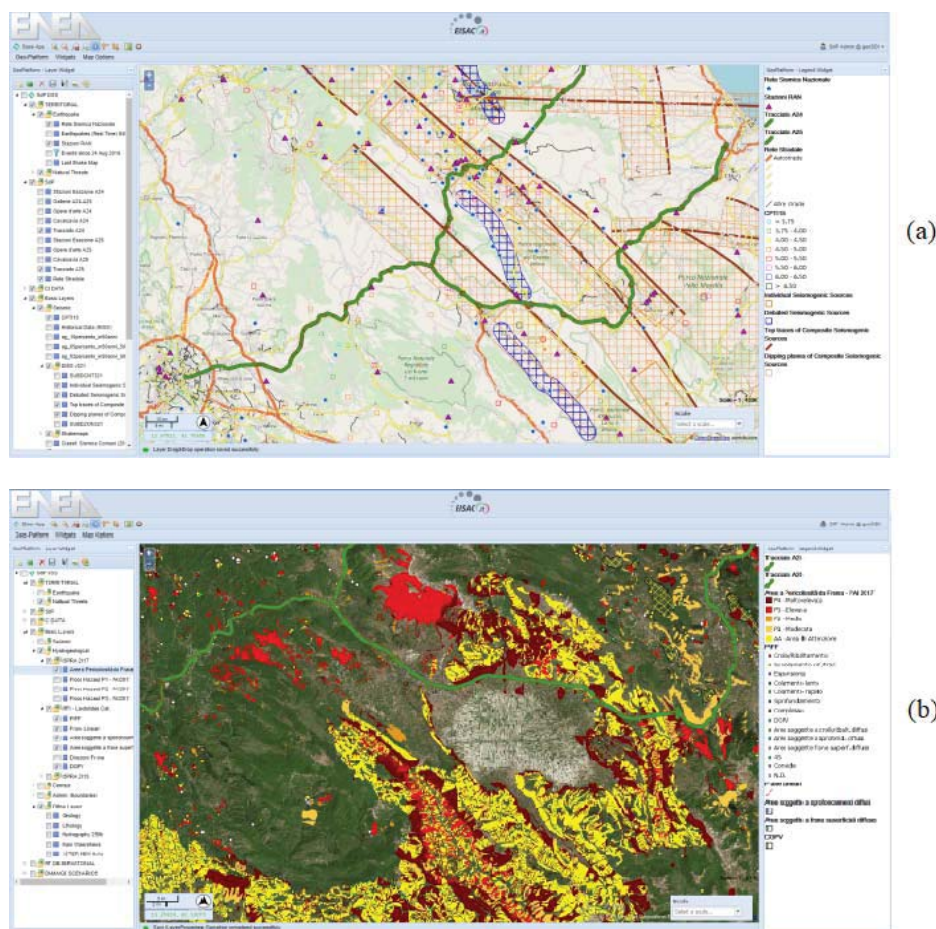

Figure 2: Example of geodata included in CIPCast DBs: (a) known faults location from INGV; and (b) landslide risk maps from P.A.I. (Piano Assetto Idrogeologico).

As far as the characterisation of viaducts or other artefacts are concerned, CIPCast can interface with external databases, via webservices, to collect and collate any already existing information thus avoiding duplication of data and waste of time. The idea is actually to promote the creation of a standardised interoperable platform, connected to CIPCast that will collate any relevant databases for viaducts or other road artefacts and that will allow to record new data [9]. As a matter of fact, since several years, ENEA, as part of the PELL (Public Energy Living Lab) project supported by the Italian Ministry of Economic Development,

MISE, has been promoted and boosted the digitization of data<sup>4</sup> and information related to the public administration, with special focus on energy-intensive and strategic infrastructures. The PELL standardised platform is already operative in several Italian municipalities for Public Lighting (PELL-IP, i.e. “Illuminazione Pubblica” in Italian) and is under development as far as schools [10, 11] and hospitals (PELL-Edifici, i.e. PELL-buildings) are concerned. For a possible PELL-viadotti [9] (i.e. Pell-viaducts), the idea would be: to collate, among others, data already included in national catalogues such as the “National Informatic Catalogue of Public Structure”, AINOP<sup>5</sup>, launched and managed by the Italian Ministry of Infrastructures and Transportation, MIT; to digitalise data that might have been collected in paper form by the PdCM (schede livello 1-2 ponti); to store, in a digital format, the data that need to be newly collected according to the forms expressly set by Linee Guida of the Italian MIT [2].

CIPCast-DSS for road networks (Figure 3) allows road network operators and emergency managers to gain, via a user-friendly WebGIS interface, real-time information on the position and extent of the ground motion and induced seismic hazard, in the aftermath of an earthquake event, as well as an estimate of the possible damage and impacts suffered by their network, that is continuously updated and made more reliable thanks to the flow of key performance indicators, KPIs, calculated from data collated through sensors deployed on some monitored components of the network.

In the first instance CIPCast DSS allow to visualise the position (coordinates of epicentre and hypocentre depth) and wave magnitude,  $M_w$ , of any occurring seismic event (overcoming the  $M_w=3$  threshold), in real time as soon as the information are made available by INGV (generally few minutes after the event).

Based on that, ground shaking maps are immediately computed by automatically implementing Ground Motion Prediction Equations (GMPEs) that can account also for possible site amplification. At the time, the GMPE provided by Bindi et al. [12] is implemented, but any other GMPE can be considered. The availability of this first estimate of the extent and severity of the seismic ground shaking along the road network allows identifying the segments and critical components, such as viaducts and embankment, that have presumably sustained higher accelerations and displacements and that might be worth inspecting as soon as possible. Possible warning about any reached threshold for the possible occurrence of earthquake-induced hazards (e.g. rockfall, landslides, permanent land deformation, liquefaction, fires following earthquake, etc.) or of any concurrent hazardous situation (e.g. severe/extreme weather, forest fires, flooding, etc.) are on the same time released by CIPCast. The official INGV shakemaps<sup>6</sup> are substituted to the simulated ones, as soon as they are made available (generally within an hour after the event).

Based on the simulated shake maps first, and on official shake maps then, a first estimate of the possible earthquake-induced physical damage to the main viaducts is performed by CIPCast implementing simplified approaches (Tier 1 and 2 approaches as explained in Section 4), based on the shaking sustained and accounting for any further possible concurrent hazards if necessary. Simultaneously, if a monitoring system is installed on viaducts, CIPCast can tune complement the estimation with the KPIs resulting from the data collected by the sensors (Tier 3 approach) thus allowing to obtain a more reliable assessment of the actual condition of the structure.

<sup>4</sup> According to the standards set by AgID, Agency for Digital Italy (<https://www.agid.gov.it/en>)

<sup>5</sup> <https://ainop.mit.gov.it/portale/#/>

<sup>6</sup> <http://shakemap.rm.ingv.it/shake4/>

Thanks to all the aforementioned real-time assessment, the most affected segments of the road are identified (Figure 3), and useful information on the residual functionality of the highway networks and on possible safe paths to evacuate the traffic can be evaluated. Through all the information displayable on the WebGIS interface of CIPCast, the asset managers can perform a more aware and participated decision-making process towards a safer and more effective emergency management.

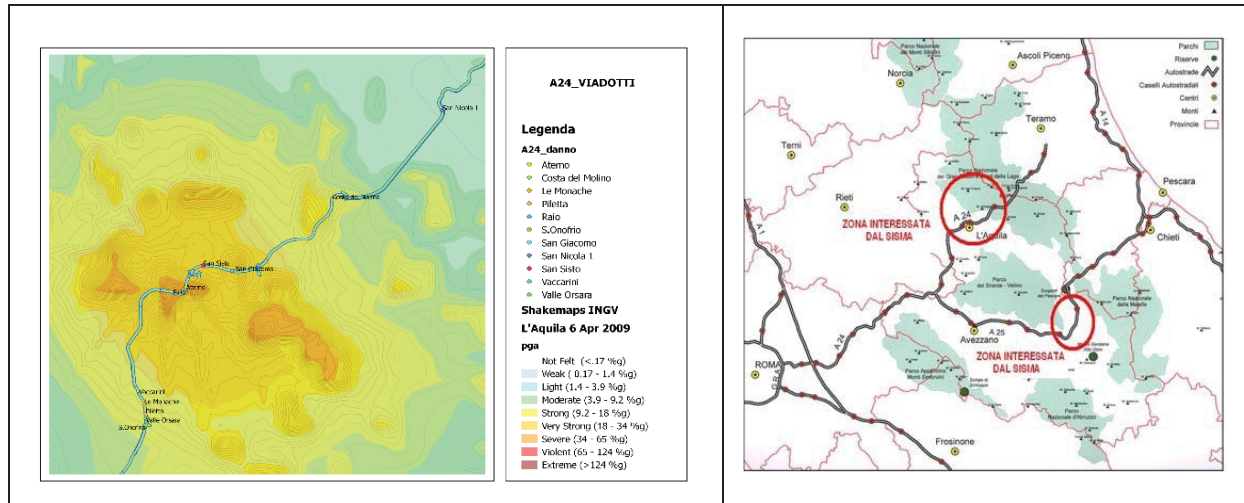

Figure 3: Ground shaking map of the April 6, 2009 L'Aquila Earthquake, overlaid with the highway route; the more severe damage to viaducts were actually identified in the viaducts located in the areas that experienced higher ground shaking.

#### 4 RISK INDICATOR AND SHM IN THE ACTIVE MANAGEMENT OF SEISMIC EVENT

During seismic emergency, as said before, CIPCast can evaluate the damage and the safety of viaducts through different methods based on the available information.

In CIPCast, three different tier of damage estimation would be implemented. Each tier corresponds to a different reliability which depends on the number of information required by the method of damage assessment. In Table 1, the three adopted tiers, in order of reliability, and their features are summarized.

For each tier, a Key Performance Indicator for the functionality level  $KPI_{SLO}$  and the damage level  $KPI_{SLV}$  can be defined to quickly evaluate the state of a bridge (Table 2) and actuate the most appropriate emergency plan.

##### 4.1 Tier 1 approach: empirical fragility curves

The first tier assesses the damage using fragility curves, which represent the probability of exceeding a predefined damage state (DS) as function of engineering demand such as peak ground acceleration (PGA), spectral acceleration (Sa) or spectral displacement (Sd).

A fragility curve can be defined through analytic or empirical methods. Analytic methods required a number of information too high to be used as a first level of damage assessment. So, CIPCast DSS implements the empirical method defined in the framework of RISK-UE project, based on empirical data collected after different seismic event.

The method divides viaducts into 15 categories, based on the parameters summarized in Table 2 and Table 3, and defines 4 different Damage State:

- D1: Minor damage,
- D2: Moderate damage,

- D3: Extensive Damage,
- D4: Complete Damage.

	Required information	Demand Parameter	Approach	Risk or damage KPI
Tier 1	Material, Column Bent Type, Span, Continuity Design (conventional or seismic) and Skew angle	Spectral acceleration $S_a(1s)$	Fragility curves	KPI <sub>1</sub>
Tier 2	Geometry, Material, Construction details and all the information to create a numerical model of the bridge	Time-history acceleration of the seismic event at the base of the structure	Numerical Model	KPI <sub>2</sub>
Tier 3	Geometry, material, construction detail	Quantity registered by SHM system	SHM	KPI <sub>3</sub>

Table 1: Tiered Approach.

Functionality level	KPI <sub>SLO</sub>	Damage level	KPI <sub>SLV</sub>
Operative bridge	<1	Low	<1
Bridge to verify	=1	Medium	=1
Inoperative bridge	>1	High	>1

Table 2: Value of KPI to evaluate the state of a bridge.

Material	Column Bent Type	Span Continuity	Design	Category
Concrete	Single	-	Conventional	1
			Seismic	2
		Simple Support	Conventional	3
			Seismic	4
	Multiple	Continuous	Conventional	5
			Seismic	6
		Simple Support	Conventional	7
			Seismic	8
		Continuous	Conventional	9
			Seismic	10
Steel	Multiple	Simple Support	Conventional	11
			Seismic	12
	All	Continuous	Conventional	13
			Seismic	14
	Other	-	-	15

Table 3: Risk-UE classification of bridges.

For each category, the method allows to define the probability of exceedance of the predefined damage states, knowing:

- The skew angle, i.e. the angle between the principal axis of minimum inertia of the pier and a line normal to roadway centreline
- The spectral acceleration at  $T=1s$  ( $S_a(1s)$ ) obtained from the response spectrum of the considered earthquake
- The number of spans.

Fixing the probability of the Damage State for which the viaduct is considered inoperable (SLO), and extremely damage (SLV), the value of the  $S_a(1s)$  inducing such states is defined respectively as  $S_{a\_SLO}$  and  $S_{a\_SLV}$ . For example, D2 and D3 levels of damage can be considered respectively to assess the spectral acceleration of the functionality level and the damage level. These values can be compared to the  $S_a(1s)$  of the response spectrum of the considered earthquake. Therefore, two KPIs can be defined by equations (1) and (2), respectively for the functionality level and the damage level.

$$KPI_{1(SLO)} = \frac{S_a}{S_{a(SLO)}} \quad (1)$$

$$KPI_{1(SLV)} = \frac{S_a}{S_{a(SLV)}} \quad (2)$$

## 4.2 Tier 2 approach: numerical models

The second tier assess the damage through a numerical model of the bridge. The required information on the viaduct increases with respect to tier 1. In order to create the numerical model, at least the following information are required:

- Structural type
- Materials and their properties
- Detailed geometry
- Construction details

If more information, such as presence of degradation phenomena, are known, the reliability of the method increases.

After the seismic event, based on the available information on both the earthquake and the structure, a linear or nonlinear analysis of the viaduct can be performed, and the dynamic response of the structure can be assessed. Some relevant parameters can be obtained to define the state of the viaduct. For example, for bridge with simple supported beams, considering an elastic numerical model, the following parameters should be determined:

- The horizontal displacements  $\Delta_t$  and  $\Delta_b$ , at the top and at the base of the piers, respectively, in order to calculate the drift of the pier  $\delta_p$
- The rotations  $\theta_t$  around the horizontal axis, at the top of the piers
- The horizontal relative displacement  $\delta_t$  between the deck and the top of the piers, if any
- The rotation  $\theta_b$  of beam section at the bearings
- The vertical displacement  $\delta_0$  of the beam at the half span

If a non-linear analysis is carried out, also the rotations  $\theta_b$  around the horizontal axis, at the base of the piers, should be evaluated. These parameters are simply represented in Figure 4.

In CIPCast DSS, the value of these parameters is compared to different threshold value, determined in order to detect the the functionality level and the damage level. Naming  $X_i$  the i-th parameter assessed from the model and  $X_{i(SLO)}$  and  $X_{i(SLV)}$  the threshold value,

respectively for the functionality and the damage level, the key performance parameters are defined by equations (3) and (4), respectively.

$$KPI_{2(SLO)} = \min \left( \frac{X_i}{X_{i(SLO)}} \right) \quad (3)$$

$$KPI_{2(SLV)} = \min \left( \frac{X_i}{X_{i(SLV)}} \right) \quad (4)$$

Figure 4: Relevant parameter to assess structural damage (tier 2).

#### 4.3 Tier 3 approach: SHM data processing and integration in the assessment

The third tier considers the use of a Structural Health Monitoring SHM system. In the following, the procedure to design a SHM system is reported:

- 1) Achievement of an accurate knowledge of the structure
- 2) Definition of the purpose of the monitoring system
- 3) Design of the monitoring system
- 4) Definition of the modality of data acquisition
- 5) Definition of the algorithm to elaborate the data
- 6) Choose of the interpretative model
- 7) Definition of the management process

Knowing the structure and the purpose of the monitoring, the SHM system must be design considering a great number of issues [13]. The monitoring time window (temporary or permanent system), the kind of sensors (inclinometers, strain gauges, displacement sensors, accelerometer...), the technologies (MEMS sensors, optical fiber sensors...), and instruments layout are chosen based on the scope of the monitoring [14].

In order to assess the actual health condition of a bridge during an earthquake, a permanent SHM system is required. The sensors work 24/7 but, to reduce the memory dimension of the data storage, the data recording starts only after a fixed number of sensors exceed a threshold value. So, CIPCast DSS receives, almost immediately, only the recordings of meaningful seismic events. For this purpose, different kind of instrument layout can be considered.

To immediately obtain time-histories of the same quantities evaluated by a numerical model and compare them to the threshold fixed value to eventually activate a state of alert or

emergency, with reference to a viaduct with simple supported beams, the following instruments layout can be used:

- displacement sensors (LVDT) at the top and base of the piers to measure their horizontal displacements,
- inclinometers at the top and base of the piers to measure their rotation around the horizontal axis,
- relative displacement sensors, for example radar sensor, between the header and the deck beams to monitor their relative horizontal displacement, if any,
- inclinometers on the deck beams to measure their rotation around the transversal axis,
- vertical displacement sensors of the beam at the half span.

This layout represents the minimum number of sensors required to assess the displacement of the structure only through a SHM system. Actually, for very different reasons, a smaller number of sensors could be used. In this way, there are not enough recording data to assess the state of the structure and the information must be updated with some parameters obtained performing a time-history analysis on the numerical model. The time history analysis is always possible if, at the base of the structure, 3 accelerometers are installed in three different perpendicular directions.

Another instruments layout, involving accelerometers, can be implemented. In this case, the following layout can be used:

- at the ground: 3 accelerometers to measure its acceleration along the longitudinal, transversal, and vertical directions,
- at the pile caps: almost one accelerometer along longitudinal, transversal, and vertical directions. If a more accurate evaluation is required, almost three unaligned sensors for each direction must be settled,
- on top of the piers: almost two accelerometers along the longitudinal direction and one along the transversal direction,
- on the beam: more sensors are required to properly assess its behaviour. The essential sensors are three unaligned vertical accelerometers: one (two) sensor at one-third of the span and two (one) sensors at three-third of the span. In addition, two unaligned accelerometers along transversal direction can be settled, one at one-third and the other at two-third of the span. Furthermore, one or two sensors in longitudinal direction can be disposed.

The values of the recorded acceleration provide some indication about the stress of the structure and, integrating the signal, information on velocity and displacement can be obtained.

However, this kind of pattern is commonly used to assess the dynamic properties of the bridge during an earthquake. Through a frequency domain analysis, the firsts modal shapes and their frequencies can be obtained. These values, evaluated for different earthquakes, can be compared, as shown in Figure 5, for the case of Cesi viaduct. The frequencies vary between the different seismic events and they decrease when the Arias Intensity of the Earthquake, calculated at the base of the bridge, increases. The strongest seismic event occurs on October 30, 2016. After this event, the frequencies returned to their initial values. The structure showed an elastic behaviour and, probably, the decrease of the frequencies is caused only by a non-linear behaviour [15].

To achieve a full representation of the health condition of the bridge both the first and second proposed layout can be implemented. Figure 6 shows an example of layout implemented in the monitoring of the jetty of Manfredonia. Figure 6(a) shows the accelerometer layout, which is repeated every six spans. Figure 6(b) shows the displacement sensor layout of a span.

Figure 5: First natural frequency of Cesi viaduct during some consequent earthquakes.

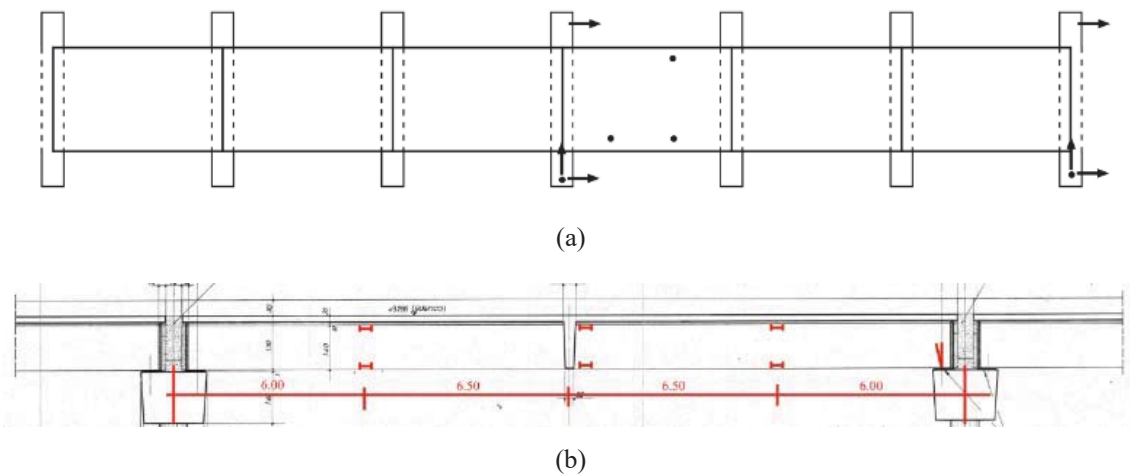

Figure 6: Layout of the (a) accelerometer and (b) displacement sensors for the jetty of Manfredonia.

This kind of monitoring system is useful also to assess the behavior of the structure in serviceable condition, considering ambient and traffic-induced vibrations [16]. Decreasing the threshold values which activate the data recording, CIPCast DSS can receive data of potential dangerous situation caused by travelling loads. The SHM efficiency increases if Weight In Motion (WIM) systems are included. These systems allow to obtain the weight and the speed of the vehicle crossing the bridge. Knowing this information, if, for equal weight and speed of vehicles, the deformations increase, the structure can be damaged. Detected the damage, the maintenance works can be scheduled.

In order to obtain complete information on the bridge status, also temperature sensors and weather control units, which measure humidity, air pressure, intensity of rain, and intensity and direction of wind, must be installed.

The analysis of all these sensor data allow to accurately define the actions on the bridge both in seismic and serviceable condition and, so, to better understand the structural response

of the viaduct and promptly detect dangerous situations. An example of such integrated and complete SHM systems is represented by the new San Giorgio bridge [17].

Depends on the features of the SHM system implemented on a bridge, the KPIs could be defined differently. The purpose of the authors is to define suitable KPIs for the most common situations.

## 5 CONCLUSIONS

After a briefly overview on the worldwide initiatives to promote the resilience of Critical Infrastructures and on develop Decision Support System for the management of the road networks, the features, and potentialities of the CIPCast DSS in use at EISAC.it have been described.

CIPCast DSS is a complex, yet user-friendly technological platform including different interoperable tools that enable the monitoring, the analysis, and the risk assessment of Critical Infrastructure. CIPCast DSS gathers and connects different vertical tools and through a powerful WebGIS interface, allows end-users to query databases DBs and to run simulation for supporting what-if analysis and decision-making processes. In the aftermaths of an earthquake, CIPCast DSS can effectively support the assessment of the residual functionality of the highway network. The paper has outlined the approached implemented within CIPcast and has originally introduced Key Performance Indicators, assessed from SHM system data, that CIPCast can use to tune and make a reliable estimation of possible damage. Therefore, CIPCast can assess the impact on the highway network functionality through simplified approaches, allowing an informed and aware decision-making process in the aftermath of seismic emergencies. The integration between CIPCast and SHM systems installed on viaducts, can effectively contribute to create “Smart Highway”, where different tools, analysis method and technologies work together 24/7 to ensure the resilience of the highway system.

### Abstract

*Exposure to aggressive environmental agents, aging and extreme weather events can seriously affect the performance of historical steel bridges. In the last decades, the need for diagnostic and monitoring of existing steel bridges became a huge widespread issue, as some recent catastrophic events pointed out (Mississippi River bridge, Minneapolis, Minnesota 2017; Kinzua Bridge State Park, Pennsylvania 2003). In this context, the need for monitoring and risk analysis of existing structures became an important concern for holders and administrators that are responsible for the construction operability and user safety. In particular, the issue of bridge inspections recently arose in the Valencian region (Spain) since a large number of railway riveted steel bridges were built between the end of the 19th and the beginning of the 20th Century. Today, after more than 100 years of existence, many bridges need repairing or strengthening interventions due to changes in service requirements or pathologies. This paper proposes a methodology for the identification of an analytical failure tree related to the structural response of the historical steel bridges located in the Valencian railroad network considering different critical phenomena and extreme events. Firstly, a suitable investigation plan has been developed to identify the typological, geometric, material and conservation characteristics of a case study. Subsequently, specific diagnostics (i.e. identification of the critical elements under traffic loads) is performed through a numerical model of the bridge calibrated by using the results of on-site static and dynamic tests. Once the critical elements are identified, some failure scenarios considering corrosion, fatigue and extreme events (e.g. earthquakes) are hypothesized in order to forecast consequence scenarios and achieve a failure tree of the bridge.*

---

## 1 INTRODUCTION

Exposure to extreme natural events, aggressive environment and aging can compromise the structural performances of existing historical steel bridges jeopardizing the safety of users and of the bridge itself [1,2]. The dissemination and knowledge gained from recent failures have contributed to show the need for safe constructions, especially for critical infrastructure systems, with a high patrimonial value. Indeed, in the last decades, some recent catastrophic events pointed out the necessity of diagnosing and preventing serious damages and consequent collapse. Some of the recent catastrophic collapses of bridges occurred in Minnesota 2017 (Mississippi River bridge) and Pennsylvania 2003 (Kinzua Bridge State Park). Consequently, the perception of the society about historical steel bridges safety has changed radically, leading to the need of defining reliable tools for investigation, diagnostics mapping particular natural disasters [3,4].

The problem is highly widespread also in Europe, where *steel railway bridges* characterize the constructive heritage of the past century and are spread throughout the Countries even in small towns [5]. Indeed at European level, one of the main priorities of Horizon Europe (regarding secure societies) is to face the challenge of “*enhance the resilience of our society against natural and man-made disasters, ranging from the development of new crisis management tools to communication interoperability, and to develop novel solutions for the protection of critical infrastructure*”. Beyond this, *bridges collapse* is also dealt at a global level. United Nations’s Agenda 2030 identifies in the section “*sustainable cities and communities*” the following important topics: a) “*provide access to safe, affordable, accessible and sustainable transport systems*”, and b) “*reduce the number of deaths and the number of people affected and substantially decrease the direct economic losses relative to global gross domestic product caused by disasters*.”

In the related literature, there are numerous studies concerning the investigation and diagnostics of existing old structures [6,7,8]. These studies confirm that the design and construction criteria of the past do not consider a number of key principles to ensure the structures durability. In addition, the current service loads on the bridges are usually greater than those expected in the design phase of the past, due to the modern increase of people and freight transportation. As a result, there are many inadequacies and weaknesses in the existing steel bridges, particularly in their conceptual designs and structural details to resist cyclic loads.

A study of the ASCE Committee on Fatigue and Fracture Reliability [9] showed that eighty to ninety percent of failures in steel structures were related to *fatigue* and fractures. Vibrations, transverse horizontal forces (e.g. wind), distortions of member cross-sections, localized and diffused defects (such as corrosion damages) represent concurring causes of fatigue damage [10]. In addition, old bridges are usually characterized by their riveted connections and this is actually one of the weakest points of this type of steel structures. In this field, some research studies developed extensive tests concerning fatigue strength of rivets under shear loads demonstrating the insufficient performance level of this type of connection [11].

In this context, it is fundamental to investigate the contemporary presence of different typologies of damages in the *steel railway bridges* in order to understand the possible arising of concatenated failures. Some authors investigated how to include different typologies of damages in Finite Element Method (FEM) models [12]. In addition, fault trees are useful tools to get a complete overview of the possible arising of concatenated failures of different typologies (*fatigue*, *corrosion* damages, *seismic* damages) [13]. On the other hand, there are few attempts to connect a fault tree with a numerical FEM model. Typically the fault trees are heuristic approaches that only provide a decision support linked to the monitoring of the bridge. Research

and approaches to achieve the fault tree from the results of a structural model are missing in related literature.

This paper proposes a methodology to derive a fault tree from a FEM model (in this case calibrated by static and dynamic tests performed on-site). Hereafter, this novel graphical tool is named Analytical Failure Tree (AFT). Compared with the classical fault tree, the proposed AFT is not based on a heuristic approach, whereas it is achieved by numerical analysis and forecasting scenarios. In addition, this novel tool offers the advantage not only to numerically identify the component level failures (basic event) that cause the system level failure (top event) but also provides the possibility of displaying the failure events on a timeline. This is a useful tool also for stakeholders which can easily predict the remaining service life of the considered structure.

The proposed procedure is applied to a riveted steel bridges located in the Valencian railroad networks (Valencia region, Spain).

Particularly, the approach is articulated in three phases:

Firstly, a suitable investigation plan provides useful information (typological, geometric, material and conservation data) to characterize the bridge and its elements. The first step of the investigation plan is devoted to acquire geometrical information of the bridge. The second step provides useful historical data clarifying the history of the past structural interventions. The third and last steps of the investigation plan regard static and dynamic load tests performed directly on the bridge where a tailored monitoring system is installed to collect displacements in critical locations and stress/strains in significant structural components.

Secondly, starting from the information retrieved from the investigation plan, a FEM structural model of the bridge can be realized. The FEM model is calibrated exploiting the results in terms of strains on the monitored members by static and dynamic tests performed on the bridge and modal properties achieved by on-site measured vibrations.

Thirdly, phenomena such as corrosion, fatigue and other possible extreme events can be included and simulated with the FEM analysis. In this third phase, the procedure to derive the analytical failure tree of the bridge is explained. Moreover, by means of the FEM structural model simulating a different typology of damages and initial condition, it is possible to hypothesize different scenarios and consequently different analytical failure trees can be obtained.

## 2 THE HISTORICAL BRIDGES OF VALENCIAN RAILWAY NETWORK

In *Valencian region* a large number of *riveted steel bridges* were built to create the railroad network from the middle of the 19th century to the first decades of the 20th century when the use of steel in bridge construction was widespread. After more than 100 years of existence of this railroad network, many bridges need repairing or strengthening interventions due to changes in service requirements or pathologies. In addition, since the steel bridges have been subjected over the years to an increasing number of train passages (which means a large number of load cycles from the beginning to nowadays), the *fatigue* phenomena could affect their remaining life. In particular, fatigue often leads to a brittle fracture that, joined with a typical low level of redundancy of these types of structures, produces a high risk of collapse. Figure 1 shows two examples of old steel bridges in the Valencian railroad network.

In the last decades, the need for diagnostic and intervention of existing structures became a huge widespread issue for holders and administrators that are responsible for the construction

operability and user safety [14, 15]. In this context, an analytical failure tree of the bridge can be of great help in evaluating the diagnostic and monitoring of the structure.

**Figure 1.** Two examples of old steel bridges in the Valencian railroad network: “Quisi” (left) and “Ferrandet” (right) bridges.

## 2.1 The case-study bridge

The proposed methodology to derive an analytical failure tree from a FEM model is applied to the “Quisi” riveted steel bridge located in the Valencian railroad networks (Valencia region, Spain). The “Quisi” bridge is a multi-span truss deck bridge connecting the towns of Alicante and Denia, built between 1913 and 1915, which currently is still in-service within the Spanish railway network.

## 3 THE INVESTIGATION PLAN TO THE CHARACTERIZATION OF THE BRIDGE AND ITS ELEMENTS

The investigation plan procedure is devoted to identifying the geometrical, typological, dimensional and material information to characterize the bridge and its elements. In addition, this investigation plan provides useful information to realize and calibrate an effective FEM structural model able to simulate the performance of the bridge under a given load condition.

A preliminary historical analysis of the bridge is performed in order to retrieve the historical documentation useful to correctly identify the construction technique and be aware of possible modifications after construction. After achieving the documentation, the geometrical and visual survey can complete the information to obtain the geometric inspection of the complete system. Finally, static and dynamic load tests are performed directly on the bridges. Consequently, the FEM structural model can be realized, specific modelling assumption can be carried out thanks to the investigation and a calibration can be achieved exploiting the result of the static and dynamic load tests.

### 3.1 The investigation plan step 1: geometrical information of the bridge

The first step of the investigation plan is fundamental to identify the exact geometrical dimension of all the elements of the bridge. Useful geometrical and technical design documents of the bridge are retrieved and combined with no site investigations. In addition, in this step, photogrammetric processes of images acquired by drones or LiDAR techniques [16,17], can be used to acquire geometrical data which can be directly used to generate FEM models. A brief description of the resulting geometric and constructive features of the bridge is reported as follows. The bridge exhibits six spans for a total length of approximately 170 m. The first two, and the last two spans exhibit an isostatic structural scheme with simply supported deck trusses (approximate length 21.00 m). Conversely, the central spans (the third and the fourth) are characterised by a continuous truss deck (hyperstatic) having a total length of 84 m. The truss deck

is composed of two main truss beams, connected by transverse (i.e. floor) beams (which, in turn, sustain the stringers) and secondary lateral bracing systems at the level of the upper and lower chords. The two central spans present a continuous structural scheme, while the four lateral ones the scheme is isostatic.

The *sub-structure* system is constituted by 5 steel braced towers. The bracing system is arranged in panels, composed of X-bracing systems, considering the longitudinal and transverse direction of the bridge, respectively. At the top of the steel towers, 0.75 m-high beams are placed to absorb the gravity loads from the bearings. The legs are battened steel members: two built-up C-shaped parallel steel profiles are connected by steel plates, one per 0.85 m, creating an open-box cross-section. Rivets are used to connect the different steel elements together in each member. At the bottom of the steel towers, steel anchor bolts attach the legs to the masonry foundations. Figure 2 shows the geometrical drawing of the investigated bridge.

**Figure 2:** The geometrical drawing of the investigated bridge.

### 3.2 The investigation plan step 2: the historical analysis

After 100 years of useful life, the investigated bridge presents some structural criticalities related to corrosion and fatigue damages due to the operation time. In addition, the structure was designed and built according to the type of trains and railway traffic of the 20th century. In order to improve the structural safety of the bridge under the current conditions of use, in 2018 it underwent a substantial retrofit intervention. In this intervention, some reinforcing-plates were applied between the upper chords of the deck and the longitudinal members, to allow these elements to work together against the horizontal braking forces, in order to reduce the stresses in the cross beams. In addition, the dimensions of the upper and lower chord of the side members have been increased through the application of two additional bolted plate (8 mm-thick). Figure 3 emphasizes the intervention in the lower chord showed red in the photo (left part of the figure) and in a section of the structural detail (in the right).

**Figure 3:** Example of the intervention in the lower chord.

The last important retrofit intervention regards the replacement of bearing devices. Pot bearings (i.e. confined elastomeric bearings) are placed on the top of the steel towers and on the masonry abutments, preventing relative displacement between the deck and the substructure members in the transverse direction, while allowing longitudinal thermal deformations. Shock transmitters are also present to ensure the transmission of longitudinal seismic forces from the truss deck to the supporting steel towers.

### 3.3 The investigation plan step 3: static and dynamic load test

Beyond the geometrical dimension, the second important result of the investigation plan regards the mechanical and structural characteristics of the bridge.

Some mechanical tests (according to EN ISO 6892-1) [18] are performed in order to identify the characteristics of the materials. All the tested samples showed consistent results in terms of both yielding and ultimate strengths (Table 1.)

Sample	Yielding strength [MPa]	Ultimate strength [MPa]	Elongation [%]
Quisi	271	399	32

Table 1: Quisi tensile test results.

A *static load* test is performed: a train composed of two wagons, representative of the real service loads, is placed at the middle of each span and the stabilized *maximum deflection* of the truss is measured. Furthermore, the deformations in some significant truss components are registered thanks to the numerous strain and displacement sensors (Figure 4). In addition, a dynamic test is performed, in which a moving train travels on the bridge (speed of 30 km/h) and the strains and stresses of significant members are evaluated. This latter test allows for measuring bridge dynamic parameters such as the *modes of vibration* and *natural frequencies* by using a set of accelerometers during the same test.

**Figure 4:** Static and load test on the bridge.

#### 4 THE CALIBRATION OF THE STRUCTURAL MODEL

The FEM model is realized with the software SAP2000 (Computer and Structures INC (CSI). SAP2000 - Structural Analysis Program 2018) by exploiting the results of the described investigation plan. Figure 5 shows the structural model of the investigated Bridge. All the built-up members are modelled by single frame elements. The bearing devices connecting the trusses to the top beams of the towers are represented by linear *two-nodes links*. The elastic modulus of the steel is fixed at 210000 MPa and fully fixed foundations are considered. Rigid end zones are placed to model connection zones between the frame elements.

**Figure 5:** Structural Model of the investigated Bridge realised with SAP2000.

Some geometrical modelling assumption are necessary in order to reflect correctly the acquired information in the numerical model. In particular, the riveted connection beam-diagonal is modelled by using a fixed connection with rigid end offsets. Moreover, the isostatic span is assumed with the following external restraints: i) the fixed bearing modeled through pinned (i.e. fixed displacement) connection, ii) the movable bearing allowing a free longitudinal translation.

Figure 6 shows the connection between the isostatic span 2 (left), the hyperstatic span 3 (right) and the steel tower.

**Figure 6:** Connection between the isostatic span 2 (left), the hyperstatic span 3 (right) and the steel tower.

The structural model is calibrated in three steps: 1) identification of the fixity degree of connection between the diagonals and the chords, 2) calibration of the value of the gravity loads, 3) calibration of the model to simulate dynamic loads (the passage of the train).

#### 4.1 Calibration with static and dynamic loads

The calibration is performed via sensitivity analyses considering the variability in some modelling parameters. *Firstly*, the isostatic spans and hyperstatic spans are isolated from the model and are subjected to a load pattern representing the axle loads used for the static tests. A first calibration and sensitivity analysis concern the fixity degree of connection between the diagonals and the chords (rigid end offsets) provided by riveted connections; the frame mesh of the elements (element discretization) and Young modulus of the steel. This sensitivity analysis is carried out by hand, updating step-by-step the model and identifying the value of each parameter (or their combination) that best reflects the outcomes of the on-site tests. In this case, both the maximum deflection of the truss and the strain values are used for benchmarking the outcomes of the model.

*Secondly*, another sensitivity analysis is performed to calibrate the value of the gravity loads (considering also non-structural loads such as sleepers or rail profiles). For this aim, the results of a modal analysis performed using several mass values consistently with some assumptions about the non-structural loads are compared to the period of vibrations registered on-site. This process is repeated for one of the isostatic truss decks and the hyperstatic one.

Thirdly, a Moving Load Analysis is carried out in the SAP2000 environment simulating the dynamic load test performed on-site. This analysis leads to further refining of the previously-fixed parameters to best reflect the local strains value of some selected elements.

#### 4.2 Calibration results

The real on-site load test and the simulation performed via SAP2000 provides very similar results in terms of max deflection and first mode frequency. To provide an example Figure 7 shows that in the isostatic span the max deflection measured on-site is 5.5 mm and in the sensitivity analysis of the model, it ranges from 5.39- 6.06mm. Moreover, the first mode frequency is 8.79 Hz in the real test and ranges from 8.84 – 8.78 Hz in the sensitivity analysis of the model. These results of the sensitivity analysis demonstrate that the calibration is robust.

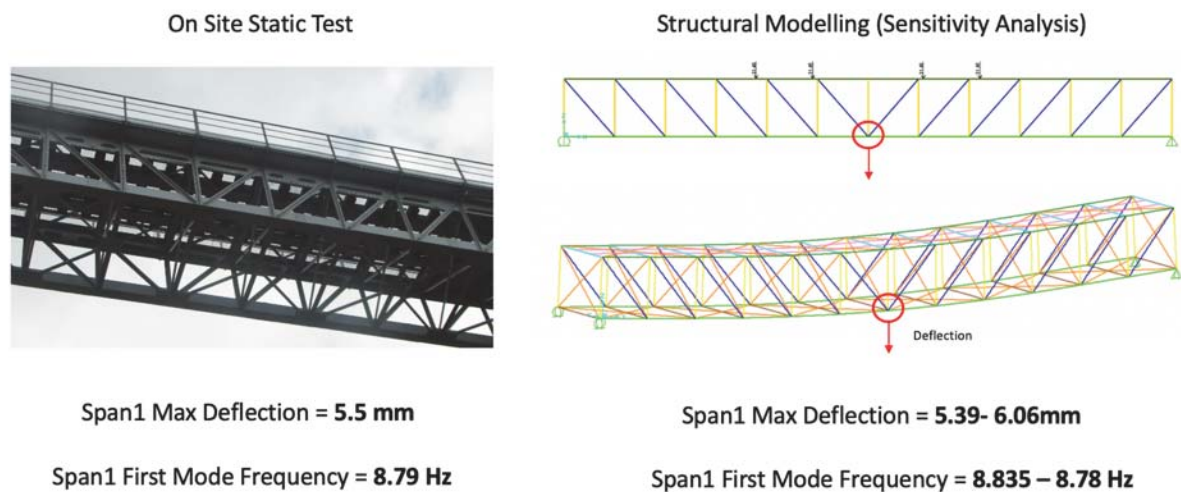

Figure 7: Static and modal test-based calibration of the isostatic Span 1

Beyond the max deflection and first mode frequency, all the strains sensors applied on the structural elements of the bridge are exploited for validating the calibration.

In particular, it is verified that the calibrated structural model (simulating the load tests) provides a deformation of the elements of the bridge compatible with that actually measured during the load tests (on which strain sensors are applied). In total, more than two hundred strain sensors are applied to the bridge, and consequently, numerous elements are available for validation. The comparison confirms the effectiveness of both the static and dynamic load simulation obtained with the calibrated structural model. Indeed, the ratio between the deformation obtained with the structural model and the deformation measured during the tests is on average equal to 0.923 (where 1 represents the perfect coherence among the two deformations). Figure 8 shows the comparison between the deformation of the elements of the Span 1 during the static and dynamic load tests, and the theoretical deformation achieved by using the SAP 2000 software.

In both in the static and load test, the only values that deviate from consistent behavior regards the cross beams. This situation occurs because cross beams take the load directly from the train. Consequently, the small differences of the model compared with the real bridge can cause overestimation or underestimation depending on the position of the train (load) on the bridge.

**Figure 8:** Comparison between the simulation (SAP 2000 software) and the real load test.

## 5 HOW TO GET AN ANALYTICAL FAILURE TREE OF THE BRIDGE

The calibrated model is the starting point to include different types of damages (e.g. corrosion, fatigue, natural hazards) in the analyses and achieve an analytical failure tree of the bridge. In this section, firstly it is explained how to include different damages in the structural model and secondly the procedure to achieve an analytical failure tree of the bridge is described. In order to have a complete overview of the possible damages of the bridge, different scenarios considering different combinations of corrosion, fatigue, earthquakes damages and different traffic volumes can be evaluated.

### 5.1 Evaluation of Corrosion Damage

The evaluation of the atmospheric corrosion is assumed on all the elements of the bridge according to the ISO 9224-2012 [19]. In particular, this approach assumes a uniform section reduction on the bridge elements. The speed of the steel corrosion depends on the type of steel and the aggressive environmental condition to which the element is exposed. In particular, the thickness reduction  $d$  is evaluated in function of the time of exposure according to the following equations:

$$\begin{cases} d_1(t) = r_{av} * t & \text{for } t < 10 \text{ Years} \\ d(t) = 10 * r_{av} + (t - 10) * r_{lin} & \text{for } t > 10 \text{ Years} \end{cases} \quad (1)$$

Where  $d_1(t)$  is the average depth of corrosion in the first 10 years of exposure,  $d(t)$  is the average depth of corrosion when the exposure time is more than 10 years;  $r_{av}$  is the average corrosion speed (during the first 10 years of exposure),  $r_{lin}$  is the average speed of stabilized corrosion (after an exposure time of 10 years), and  $t$  is the Exposure time. Moreover, the  $r_{av}$  and  $r_{lin}$  are tabulated values indicated in the ISO 9224-2012.

The reduction of the cross-section area of the elements calculated with the Equation (1) can be easily implemented in the structural model by property modifiers to the cross-section elements defined in SAP2000.

## 5.2 Evaluation of Fatigue Damage

The evaluation of the fatigue phenomenon can be evaluated according to the Miner's Rule [20]. The linear Miner's damage equation is widely used in engineering for its effectiveness and ease of application. This mathematical formulation allows for achieving the damage  $D$  of a specific element subjected to cyclic loads as follows:

$$D = \sum_{i=1}^k \frac{n_i}{N_i} \quad (2)$$

where  $N_i$  is the fatigue life of the element under some stress levels typically determined by laboratory tests and  $n_i$  is the number of load cycles of a given amplitude applied on the element. Moreover, when  $D$  is equal to 1, the component fails.

The value  $N$  can be achieved by using the curve Stress – Number of cycle (S-N) proposed by proposed in Kühn et al. [21] also applied in the Eurocode 3. In particular, some laboratory tests are performed to identify the S-N curve of the investigated bridge elements.

A previous investigation to achieve the curve S-N was performed in the laboratory of the ICITECH [22]. In particular, an upper cross beam and a full-scale bridge span of the Ferrandet Bridge was tested. The span and the cross beam have the same geometry and similar characteristics of spans 2 and 5 of the Quisi Bridge. To this aim, the results are valid for both the bridges as discussed in [22]. During the tests, Linear Variable Displacement Transducers (LVDTs) and Strain Gauge (SG) sensors were used to capture the possible nucleation and propagation of fatigue cracks.

Figure 9 shows the curve S-N of the investigated components of the bridge. In addition, an example of the application of the curve is showed in the following.

Let us assume that the structural model shows that the diagonal 12 of the Span1 suffer a load cycle of an amplitude of  $\Delta\sigma_c = 41 \text{ N/mm}^2$ . Consequently, thanks to the curve S-N it is possible to identify the amount of residual cycles before the component fails due to fatigue stress (that are approximately  $10^7$ ). It is worth noting that knowing the traffic on the bridge (number and typology of trains per day) it is possible to understand the remaining life of a component. The instant in time at which the failure occurs (considering a predetermined traffic condition) can be precisely identified.

The effects of fatigue phenomena can be accounted for in the numerical model, by appropriate reductions of the mechanical properties of the elements or by neglecting their contribution in case of fatigue failure. This operation should be performed by updating by-hand the model (e.g. no automatic procedure is available).

Figure 9: Curve Stress – Number of cycle for the components of the investigated Bridge: example of the application for the diagonal 12 of the Span1.

### 5.3 The evaluation of earthquake damage

Also the structural performance of the model under actions induced by natural hazards can be included in the analytical failure tree framework. As an example, in the case of seismic actions, state-of-the-art numerical analysis approaches (i.e. nonlinear static or nonlinear dynamic) can be performed to analyse the performance of the case-study structure under a given seismic action (i.e. code-based design action) or for a given earthquake scenario.

To this aim, a nonlinear numerical model should be adopted to predict the inelastic demand for each member during the seismic excitation. An appropriate modelling strategy should particularly consider the inelastic response of the substructure members which exhibit the highest probability to reach selected damage states, as proved in the large literature about the seismic response of multi-span bridges types [23,24]. To this aim, distributed- or lumped-plasticity strategies can be adopted. In the latter, plastic hinges should be used to predict the nonlinear axial response of bracing members (subjected to buckling or tensile yielding) and nonlinear axial-flexure response in the legs of the steel towers (Figure 10). Also, failures of the riveted connections or for shear should be considered. Appropriate recommendations about modelling and seismic analysis of truss bridges are reported in [25].

Nonlinear dynamic analyses are widely recognised as the most accurate strategies to predict the response of the case-study bridge under a given ground-motion shaking. However, such analysis approaches are very demanding in terms of computational efforts, particularly for complex structures such as steel truss bridges. Moreover, these analyses require models about the cyclic response of built-up steel members which are rarely available in the literature [26,27]. Conversely, nonlinear static procedures are less demanding with respect to nonlinear dynamic approaches. The accuracy of these simplified methods strongly depends on various assumptions (e.g. regular dynamic response) which can be not valid for typical steel truss bridges. However, according to [25], this simplified methodologies are effective for local analysis of substructure

members, such as steel towers, to identify the corresponding ductility capacity and failure mechanisms.

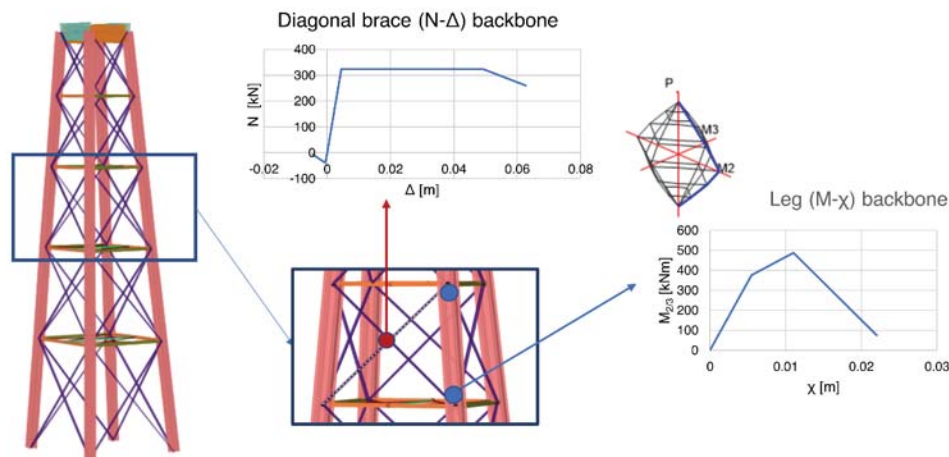

Figure 10: Modelling strategy (lumped-plasticity) for seismic response of supporting steel towers.

#### 5.4 The proposal of the analytical failure tree

In this subsection, the methodological process to achieve an analytical failure tree of a bridge is discussed. More precisely, the analytical failure tree is intended as a graphical representation developed on a timeline to show when faults can occur according to the structural model. In addition, the analytical failure tree also shows the connections among failures. A failure can be isolated without causing other consequences. In other cases, the failure can create a cascade effect. The analytical failure tree is also useful to understand the possible occurrence of serious cascade effects causing rapidly a global bridge collapse.

The analytical failure tree is obtained with an iterative process that concerns the evaluation of the amplitude of the load cycles from every element of the bridge (from the FEM model) and the related evaluation of the fatigue damages (and concurring causes) over time. In particular, the process is explained in the following bulleted list:

- 1) Initially there are no damages and the dynamic analysis is performed. Consequently, the stresses of all the elements (or components) are obtained from the FEM model;
- 2) The elements that undergo significant load cycles (named critical elements) according to the curve “Stress – Number of cycles” are considered. Fatigue and other concurring causes (e.g. corrosion) are evaluated over time by using procedures described in subsections 5.1 and 5.2;
- 3) The first element that fails in the instant  $t_I$  is identified;
- 4) The failure is shown in the analytical failure tree in the instant  $t_I$  (indicating component and cause);
- 5) The contribution of the damaged element is implemented, updating the FEM model (updated in the instant  $t_I$ ),
- 6) The new stresses of all the components (after  $t_I$ ) are obtained from the FEM model subjected to a new analysis,

- 7) If no other elements have reached a limit state it is possible to continue with the next step. If other elements have reached a limit state, the analytical failure tree and the structural model are updated by considering all the elements failed in the instant  $t_1$  and new stresses are evaluated (this step is repeated until the updating of the structural model does not cause other element reaching a limit state or a global failure is reached);
- 8) This phase is analogous to point 2. New fatigue damages and other concurring causes are evaluated over time;
- 9) The second element (or group of elements) fails in the instant  $t_2$ . If this second failure is related to the first one (instant  $t_1$ ), then it is placed on the same branch of the fault tree. On the contrary, if the second element fails is not related to the first one a new independent branch is drawn.
- 10) The process is repeated until the instant  $t_n$  is greater than a preset year or a global failure is achieved.

More in details, the rules to understand if two consecutive failures belong to the same branch are specified in the following. Let us assume the presence of two failures (a first failure in the instant  $a$ , and a second failure in successive instant  $b$ ). The conditions so that these two consecutive failures are positioned on the same branch of the failure tree are the following:

- 1) the two failures belong to the same span, or to two adjacent hyperstatic spans;
- 2) the element that undergoes the second failure (instant  $b$ ) suffers an increase in load due to the first failure (this condition can be identified when the numerical model is updated).

If these two conditions do not both occur, it means that the two damages are independent, and it is right to represent them differently on two different branches in the fault tree.

It is worth noting that in the proposed application, the failure can occur for the *fatigue* and all the other phenomena can only speed up the damage. Indeed, the *corrosion damage* causes a section reduction, that consequently can produce a premature fatigue failure. The *seismic damage* creates small structural damages (due to the low seismicity of the region in question) which in some cases can aggravate the effects to the fatigue damage. Other possible damages can occur as a consequence of the redistribution of loads after a fatigue failure. Consequently, the proposed approach is in line with the assumption demonstrated in the study of the ASCE Committee on Fatigue and Fracture Reliability [9] assessing that the failures in steel structures were related principally to *fatigue* and all the other phenomena are concurring causes that can involve the reaching of a limit state.

## 5.5 The analytical failure tree and different scenarios of the investigated bridge

The proposed analytical failure tree can consider different aggressive phenomena including corrosion, fatigue and it can also be used to understand the consequences of earthquake damages. In addition, different scenarios can be defined on the basis of the presence (with different intensity level) or absence of every aggressive phenomenon.

In particular, the *atmospheric corrosion* can produce a section reduction of the elements of the bridge. In an alternative scenario, corrosion can be avoided thanks to an effective maintenance and the use of adequate corrosion inhibitors.

The intensity of the *fatigue phenomenon* is strictly correlated to the traffic volume present on the bridge. The current traffic is about 32 trains per day, but it could be increased due to specific

needs of the region. Both the current and possible “traffic increased” scenario must be considered in order to have an exhaustive overview of the possible damage of the bridge.

The probability of occurrence of a *seismic event* of a given intensity is extremely connected to the hazard characteristics of the site. Even if the Valencian region has low seismicity, it is important to understand how the eventual presence of seismic damage would interact with other aggressive phenomena.

Consequently, it is possible to hypothesize eight damage scenarios corresponding with all the possible combination of *atmospheric corrosion*, *fatigue phenomenon* and presence or not of a *seismic event* (Table 2).

SCENARIOS	CORROSION	FATIGUE	SEISMIC EVENT
Scenario 1	No corrosion (Constant maintenance)	Current traffic volume	No seismic damage
Scenario 2	No corrosion (Constant maintenance)	Current traffic volume	Seismic event
Scenario 3	No corrosion (Constant maintenance)	Increased traffic volume	No seismic damage
Scenario 4	No corrosion (Constant maintenance)	Increased traffic volume	Seismic event
Scenario 5	Atmospheric corrosion	Current traffic volume	No seismic damage
Scenario 6	Atmospheric corrosion	Current traffic volume	Seismic event
Scenario 7	Atmospheric corrosion	Increased traffic volume	No seismic damage
Scenario 8	Atmospheric corrosion	Increased traffic volume	Seismic event

Table 2: Different damage scenarios.

For every different damage scenario, an analytical failure tree can be achieved in order to understand what types of damage could occur.

To provide an example, Figure 11 show an analytical failure tree for the Scenario 1 regarding the presence of an effective maintenance (to avoid corrosion), current traffic volume and no presence of seismic damage.

Figure 11: Analytical failure tree for the Scenario 1.

## 6 CONCLUSION

The work proposes a methodological approach to develop an analytical failure tree of historical steel bridges based on the calibration of a numerical FEM model able to include different damage scenarios in the analysis:

- i) The atmospheric corrosion phenomenon is evaluated in accordance with the ISO 9224-2012 assuming a uniform section reduction of the steel elements of the bridge.
- ii) The evaluation of the fatigue phenomenon exploits the Miner's Rule and the curve "Stress – Number of cycles" to identify the number of load cycles of a given amplitude that the element can experience before the failure.
- iii) The seismic damages can be included with state-of-the-art analysis approaches based on a nonlinear numerical model of the bridge representing its current condition.

Compared with the classical fault tree, the proposed analytical failure tree is achieved by exploiting a FEM model and numerical analysis. On the contrary, the classical fault tree is drawn based on the technician's expertise and by following a heuristic approach. In addition, the proposed failure tree has the advantage to displaying the failure events on a timeline.

The approach is applied to the real case study of a riveted steel bridge located in the Valencian railroad network (Spain) and the example of the analytical failure tree achieved for the scenario involving fatigue damaged related to 32 trains per day, absence of atmospheric corrosion and seismic damage is shown. The analytical failure tree obtained with the proposed approach can be useful for diagnostics, monitoring and forecast intervention by simulating different consequence scenarios.

Future research will perform an exhaustive investigation to achieve the analytical failure trees of several different scenarios in order to have a complete overview of the possible failures and any cascade effects on the investigated bridge.

### Abstract

Roadway networks, playing a vital role in the economic prosperity of modern societies. Recent hazardous events in Greece, for instance, the 2021 Thessaly earthquake and floods and the heavy 2019 rainfall in Crete, have demonstrated the vulnerability of roadway networks to natural hazards, resulting in severe physical damage and important economic and societal losses. Severe damage on bridges and tunnels of roadway networks is commonly related to the effects of multiple hazards that may act independently during their life. However, the literature on risk assessment of the above elements is commonly focused on the effects of one hazard, disregarding the potential interaction effects of diverse hazards in a multi-hazard environment. In this context, there is an increasing need for reasonable and effective evaluation of the multi-hazard risk of transportation infrastructure. Research project INFRARES aspires to bridge this gap by gaining further insight into the risk assessment of bridges and tunnels of transportation networks in Greece, when subjected to separated and subsequent hazards, with particular emphasis being placed on seismic and flood hazards. The present paper briefly presents a unified methodology to homogenize the single seismic and flood hazard scenarios and develop appropriate single- and multi-hazard maps for Greece to be used in risk assessment of roadway networks. Seismic hazard data, referring to rock site conditions, developed within the SHARE research project ([www.share-eu.org](http://www.share-eu.org)), is initially selected and is properly amplified to account for site effects, by employing a simplified  $V_{s,30}$  model originating from morphology and topography data of each region in Greece. The seismic hazard is estimated for a return period of 475 years. Flood hazard zones are derived for whole Greece using newly developed data from the Joint Research Center of the European Commission (<https://data.jrc.ec.europa.eu/dataset>) for the 100-years return period scenario. Using the above input, both single hazard and multiple hazard models are developed and provided in terms of maps in GIS format. The model developed within this study is expected to be a valuable contribution towards the generation of a uniform multiple hazard model for the risk assessment of critical elements of transportation infrastructure in a multi-hazard environment.

**Keywords:** Natural hazards, earthquakes, floods, multi-hazard risk assessment.

---

## 1 INTRODUCTION

The reliability of roadway networks and their components, exposed to multiple natural hazards, is on the frontline of engineering research during the last three decades since potential damage on their critical components (e.g., bridges and tunnels) is strongly related to important direct and indirect economic losses. In this context, enhancing the resilience of roadway networks is key for a safety and an economic viewpoint. Disaster resilience is defined by the National Academies as “*the ability to prepare and plan for, absorb, recover from, and more successfully adapt to adverse events,*” while “*enhanced resilience allows better anticipation of disasters and better planning to reduce disaster losses – rather than waiting for an event to occur and paying for it afterward*” [1]. To achieve such enhanced resilience, civil infrastructure systems must not only survive natural disasters, but also recover to functional levels within acceptable time and cost limits.

The spatial extent of most civil infrastructure systems, including roadway networks, and the disparity of their elements make them susceptible to a wide range of natural hazards. Bridges and tunnels are considered to be the most critical components of urban and interurban transportation systems, and as such should ensure mobility and intercity connection after extreme hazard events. Bridge damage may cause significant disruption to a transportation system, resulting in severe substantial direct and indirect losses; for instance, the Loma Prieta 1989 earthquake resulted in more than 40 deaths due to bridge damage and \$1.8 billion monetary direct losses due to damage to the transportation infrastructure [2]. Flood due to heavy rainfall may result in substantial losses, as well; for example, in 2007, heavy rainfall in the UK affected the road network with estimated cost £60 million (The Parliamentary Office of Science and Technology, Post Note Number 362, October 2010). Extreme weather conditions, associated with recorded climate changes, e.g., floods and extreme temperatures, are expected to worsen the performance of many bridges in the near future [3]. Damage on bridges due to extreme weather conditions in Greece (e.g., reported damage due to heavy rainfall in Trikala in 2016 and in Crete in 2019) is more frequently recorded during the last years. Bridge damage related to flood, scouring and ground failures may result in collapse and traffic disruption. Although to a lesser extent, natural hazards may result in damage on tunnels as well. For instance, a large number of mountain tunnels suffered significant damage during the 1999 Chi-Chi earthquake in Taiwan, as well as during the 2008 Wenchuan earthquake in China [4].

During the last 30 years, several methods have been developed for the assessment of performance and vulnerability of bridges [5] and tunnels [4, 6] against seismic and flood hazard [7]. Recognizing the significant effects of multiple hazards, as well as of climate change, on the vulnerability of civil infrastructure, the research interest has been recently shifted upon the derivation of multi-hazard fragility curves [8]. However, the lack of knowledge in this field remains significant, when referring to transportation infrastructure, including roadway networks.

Regardless of the examined system or element at risk, one of the most critical steps of any multi-risk assessment methodology is the appropriate definition of multiple hazard scenarios under which the examined system or element may be subjected throughout its life.

Based on the above considerations, the main objective of the present paper is to present briefly a framework for the development of combined seismic- flood-hazard scenarios to be used for the risk assessment of critical elements of roadway networks, i.e., bridges and tunnels, referring to whole Greece. The proposed framework helps towards a unified seismic- flood hazard model, which will be used in within the research project INFRARES (<https://www.infrares.gr/>) that aims at assessing the risk and resilience of bridges and tunnels of roadway networks in Greece against the aforementioned hazards.

## 2 INFRARES PROJECT

A comprehensive methodology for the risk and resilience assessment of roadway networks in a multi-hazard environment, will be developed in the framework of INFRARES, focusing on bridges and tunnels. To meet the objectives of the project, various methodological frameworks will be used, associated with the following steps enclosed in the definition and assessment of risk: (i) exposure: an inventory of crucial elements of transportation systems, i.e., bridges and tunnels, which may be affected by diverse natural hazards, will be developed accounting for typologies found commonly in Greece. (ii) Multi-Hazard assessment: various scenarios of distinct and multiple natural hazards will be defined, focusing on earthquakes and floods since these hazards are considered more relevant for the risk assessment of the transportation infrastructure in Greece. This step will include also the definition of appropriate measures to describe the intensity of examined hazards. (iii) Vulnerability assessment: the degree of loss on the given element or set of elements at risk, when subjected to a specific natural hazard or to a combination of diverse hazards will be calculated, by employing comprehensive numerical analyses of the selected elements, while accounting thoroughly for the effects of ageing-related degradation phenomena of the elements, as well as of Soil-Structure Interaction (SSI) effects.

A fully parametrized software will accompany the methodology, allowing for its easier application by providing the provided time-dependent, multi-hazard fragility curves for roadway bridges and tunnels. Figure 1 presents a first draft of the general flowchart of the methodology that is being developed in the framework of the INFRARES project.

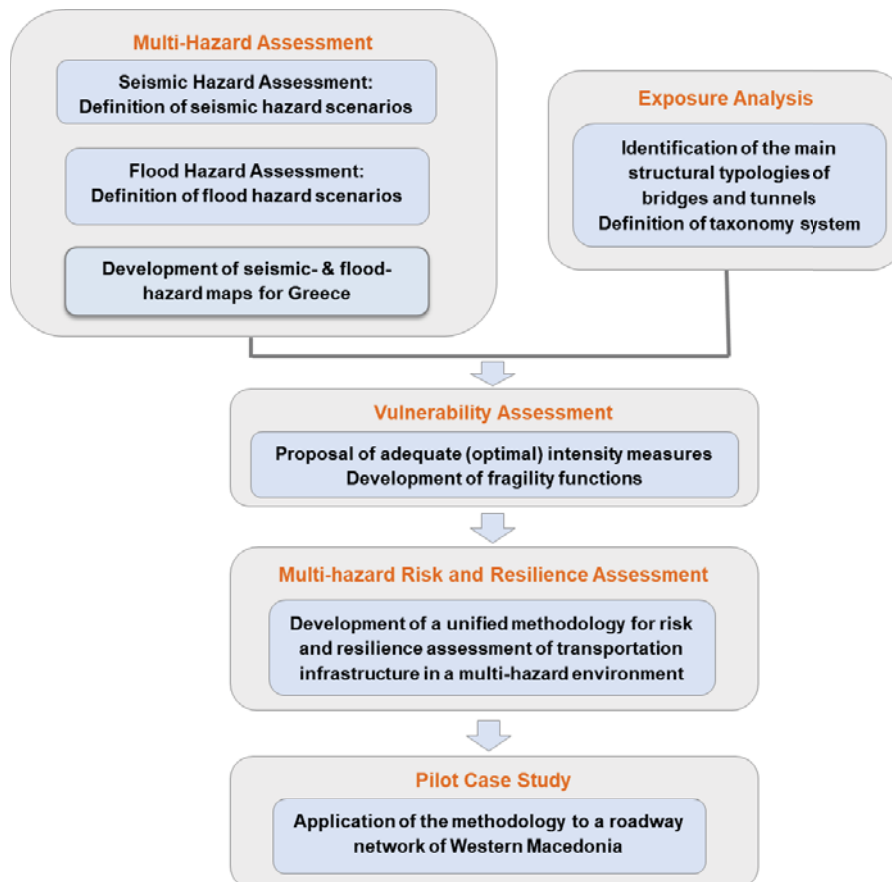

Figure 1: Flowchart of INFRARES project

In particular, INFRARES is expected to contribute on the State of the Art by providing an innovative methodology for the generation of multi-hazard maps, to be used for the definition of relevant scenarios in the framework of multi-hazard risk assessment of transportation or other civil infrastructure. In addition, new, analytical fragility curves and functions will be developed for various typologies of bridges and tunnels, and for distinct and/or combined hazards, considering in the latter case combinations of hazards that are relevant for Greece. Moreover, the damage state definitions within fragility analysis of bridges and tunnels will be case- and hazard-specific, considering different failure modes and damage mechanisms, to fill relevant knowledge gap. Finally, a resilience index will be proposed for bridges and tunnels typologies, as well as for roadway networks, referring to distinct hazards and various hazard combinations. In this context, the index will be appropriately modified so that to be applicable for multi-hazard assessment purposes. The methodology and the software could be used for rapid and rigorous pre- or post-event assessment of infrastructure or for post-event risk management, constituting very useful tools for stakeholders, operators, consultancies and public authorities.

In the following sections, we focus on one of the main steps of the methodology, namely the multi-hazard assessment. More specifically, we present an innovative methodology for the generation of multiple seismic- flood- hazard models in GIS format.

### **3 MULTIPLE HAZARD SCENARIOS FOR TRANSPORTATION INFRASTRUCTURE IN GREECE**

In the framework of the multi-hazard assessment approach adopted herein, diverse natural hazards and combined hazards scenarios are carefully selected, prioritized on the basis of the potential to cause damage on transportation infrastructure and further examined. After a thorough literature review and lessons learned from past hazards events, earthquakes and floods are selected as the most critical natural hazards for the assessment of the transportation infrastructure in Greece. Initially, each natural hazard is studied separately, while in a second phase we examine the combination of the two hazards, proposing a unified framework for multi-hazard scenarios. Both single or multiple hazards scenarios are visualized in the form of maps in GIS format, referring to whole Greece.

The main steps of the herein proposed framework are:

Step 1: Establish a ranking of the different types of natural hazards, considering potential interactions between them.

Step 2: Identify single-hazard models.

Step 3: Identify multi-hazard models, covering all potential intensities and relevant hazard interactions.

Step 4: Generate single- and multiple- hazard scenarios and relevant maps in GIS format for the assessment of transportation infrastructure in Greece.

For the sake of presentation of the framework, in the present paper, we consider for the seismic hazard the standard design/assessment seismic scenario with a return period equal to  $T_{m_s}=475$  years. For the flood hazard, we examine a design/assessment flood hazard scenario with a return period equal to  $T_{m_f}=100$  years.

### 3.1 Single hazard maps

In the present work, a unified methodology is employed to homogenize the single seismic and flood hazard scenarios. These single-hazard scenarios are displayed in the form of GIS maps and can be used for the risk assessment of any examined element. Moreover, they may be used to and develop appropriate maps for multi-hazard scenarios as discussed in section 3.2.

Seismic hazard data for rock site conditions, developed within the EU-funded research project SHARE (<https://www.share-eu.org>), is initially selected. This data is subsequently properly amplified to account for site effects, by employing a simplified  $V_{s,30}$  model, originating from morphology and topography data of the examined region. In the present study, the seismic hazard is estimated for a return period of 475 years.

More specifically, the seismic hazard estimates were extracted from the global seismic hazard map produced by Pagani et al. [89]. The hazard is expressed in terms of the Peak Ground Acceleration (PGA, as a fraction of  $g$ ) for a probability of exceedance of 10% in 50 years (equivalent to a 475-year return period) on rock (average shear-wave velocity down to 30 m -  $V_{s,30} = 760$  m/s). A detailed description of how the global seismic hazard model was developed may be found in Pagani et al. [9]. The seismic hazard analysis is performed using the OpenQuake engine [10], an open-source seismic hazard and risk calculation software developed, maintained and distributed by the Global Earthquake Model (GEM) Foundation. Recent studies on the use of the European Seismic Hazard ESHM13 [11] may be found in Riga et al. [12] and Karatzetzou et al. [13].

With reference to the flood hazard, flood hazard zones were derived for one scenario based on 100 years return period. In particular, a newly developed dataset for Europe referring to river flood hazard, was derived from the Join Research Center of the European Commission [14]. The flood hazard zones were based on the combination of river flow data, estimated through the hydrological model LISFLOOD, while the inundation simulations were performed with the 2D hydrodynamic modelling LISFLOOD-FP. Subsequently, the hazard was expressed in terms flood extent zones in different flood frequencies (e.g.,  $T=100$  means frequency 1-in-100-years).

Figure 2 portray the resulted single hazard maps for Greece for the examined seismic and flood hazards scenarios, respectively.

### 3.2 Multi-hazard maps

For the homogenization of the single hazard maps of Greece (i.e., seismic hazard map and flood hazard map, presented in section 3.1), we used a bivariate scaling system. This qualitative approach is often used to depict pairs of variables, whose mathematical combination might not be straightforward or possible, for instance, social vulnerability and natural hazards [15] or seismic and biological hazards [16]. In the herein proposed framework, we define four thresholds to classify each variable into *low*, *moderate*, *high* and *very high* hazard. These thresholds are created automatically in Arc-Gis using the quantile method. Then, we create a color matrix comprising all the combinations between the two variables. In this study, we combine the seismic hazard in terms of the PGA for the selected return period (475 years) with the river flood hazard in the terms of the percentage distribution of flood hazard zones, respectively for return period equal to 100 years. Figure 3, presents the resulted multiple-hazard map for Greece, for the examined scenarios.

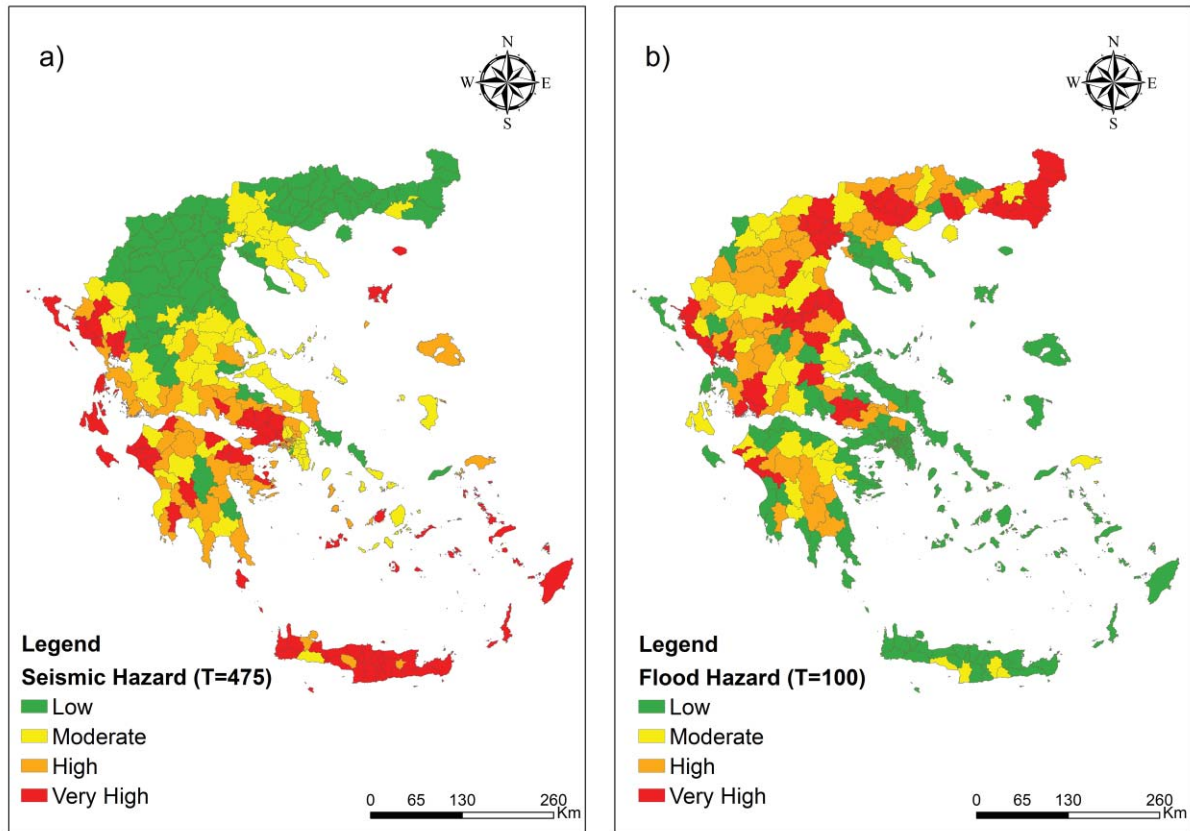

Figure 2: (a) Seismic hazard map for a return period equal to  $T_{m_s}=475$  years and (b) flood hazard map for a return period equal to  $T_{m_f}=100$  years for Greece

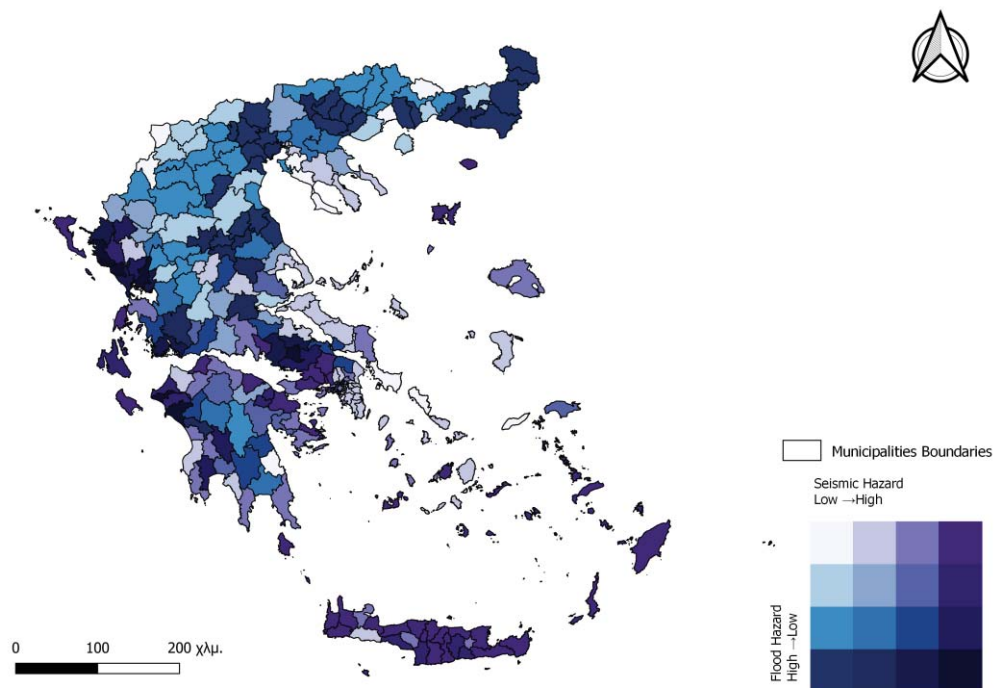

Figure 3: Bivariate map depicting the combination of seismic ( $T_{m_s}=475$  years) and flood ( $T_{m_f}=100$  years) hazard for Greece.

## 4 CONCLUSIONS

The present paper presented a unified framework to homogenize the single seismic and flood hazard scenarios and develop appropriate single- and multi-hazard maps for Greece to be used in an under-development methodology for the risk assessment of critical elements of transportation infrastructure in a multi-hazard environment. The work was developed within the INFRARES research project, which is also briefly presented.

With reference to seismic hazard; seismic hazard data for rock site conditions, developed within the SHARE research project ([www.share-eu.org](http://www.share-eu.org)), was initially selected and is properly amplified to account for site effects of various regions in Greece, by employing a simplified  $V_{s,30}$  model originating from morphology and topography data. The seismic hazard was estimated for whole Greece and for a 475-years return period scenario and plotted in a relevant map in GIS format.

Regarding flood hazard; flood hazard zones were derived for Greece from a newly developed database of the Joint Research Center of the European Commission [14] for one scenario based on 100 years return period. The resulted flood hazard was estimated for whole Greece and plotted in a relevant map in GIS format.

A bivariate scaling system was used for the homogenization of single-hazard maps referring to the above hazards. For the development of the multi-hazard map, four thresholds were automatically created in Arc-Gis to classify each hazard into *low*, *moderate*, *high* and *very high* level. A color matrix was then created comprising all the combinations between the two variables-hazards, leading to the creation of the multi-hazard map for whole Greece.

The framework presented within this study is expected to be a valuable contribution towards the generation of a uniform multiple hazard model for the risk and resilience assessment of roadway networks.

## ACKNOWLEDGEMENTS

The work reported in this paper was carried out in the framework of the research project INFRARES “Towards resilient transportation infrastructure in a multi-hazard environment” (<https://www.infrares.gr/>), funded by the Hellenic Foundation for Research and Innovation (HFRI) and General Secretariat for Research and Innovation (GSRI) under the “2<sup>nd</sup> Call for H.F.R.I. Research Projects to support Post-Doctoral Researchers”. (Project Number: 927).

### Abstract

*The cross interaction between two closely-spaced shallow foundations has been numerically investigated under static conditions and low-amplitude dynamic loading through a finite difference procedure implemented in the FLAC3D code. The motivation towards this research topic may be found in the increasingly growth of urbanization in modern metropolitan areas worldwide and in the urgent need for seismic requalification of vulnerable historical centres in ancient towns, where buildings are placed very close each other. Even though a disconnection between the superstructures exists, the response of their foundations (and that of the buildings themselves) may be coupled due to the continuity of the soil underneath. Consequently, the overall system response may be different from that predicted with reference to the simple scheme of an isolated footing or building. In the performed numerical study, the soil-foundation impedance functions of a single foundation were firstly compared to well-known literature closed-form solutions to validate the procedure from a numerical viewpoint. The analyses were then repeated with adding another footing identical to the first one and placed at a varying distance from it. The comparison between the response of the master foundation when modelled as isolated and as part of a group shows that the dynamic impedances of the footing in-group may remarkably change with respect to those of the isolated foundation. In particular, the stiffness (real part) increases at a frequency depending on footing-footing distance and the damping ratio increases or decreases depending to the type of imposed oscillation.*

**Keywords:** Soil-structure interaction, Dynamic Cross Interaction (DCI), Impedance functions, Shallow foundation, 3D numerical modelling

## 1 INTRODUCTION

With the rapid progress of urbanization, very closely-spaced buildings are increasingly being built in both large cities and smaller towns. The proximity among buildings could produce an interaction between them and, consequently, may cause a different response under both static and dynamic loading. As the former aspect concerns, the cross interaction between closely spaced footings could have effects on both settlement and bearing capacity evaluation. The first author that investigated the bearing capacity problem for a group of shallow footings was Stuart (1962) [22], who proposed to insert a sort of “efficiency factors” in the bearing capacity trinomial formula proposed by Terzaghi (1943) [23]. Depending on the width  $B$  of the footing, these corrective factors may be greater than one if the two footings are placed at a short distance  $S$  from each other ( $S < 3\div 4 B$ ), equal to one in the case of higher distance ( $S > 4\div 5 B$ ), so that each foundation behaves as isolated from the other, and equal to two in the case of  $S=0$ , i.e. when there is perfect contact between the two footings.

Under dynamic loading, the typical dynamic soil structure interaction evolves into a problem of cross interaction between multiple structures, better known in literature as Structure Soil Structure Interaction (SSSI) or Dynamic Cross Interaction (DCI). The study of SSSI may be handled with the same methods used for standard SSI problems in which a single footing (or structure) is involved. The available methods may, hence, be classified into analytical, semi-analytical or numerical approaches, experimental methods with observations on prototypes. Thanks to the rapid progress of computing procedures and hardware devices, nowadays the numerical methods are the most used approach for evaluating SSSI. Menglin et al. (2011) [11] produced an extensive literature review on structure-soil-structure interaction, in which it was highlighted that the SSSI terminology was firstly introduced into the scientific literature by Luco and Contesse (1973) [9], who investigated the interaction phenomenon between two or more buildings (modelled as shear walls) placed on rigid circular foundations and subjected to obliquely or vertically incident harmonic SH-waves. Through parametric studies, Luco and Contesse (1973) [9] found that a group of closely spaced buildings could be affected by cross interaction at frequencies close to the fundamental ones of the buildings and particularly in low frequency ranges. Any vibrating foundation was found to spread a wave field that could be seen as a disturbance affecting the adjacent foundations. In [9] the dynamic excitation was represented as an external load or a seismic wave field. In the first case, the response of the foundation was assessed through the frequency-dependent soil-foundation dynamic impedance, representing the soil-foundation response to the inertial action transmitted by the superstructure and linking the force (or moment) acting on the foundation to its displacement (or rotation). In the second case, the motion at the base of the structure was determined.

Based on the substructure method, Betti (1997) [19] proposed a methodology for the analysis of the 3D cross-interaction between two massless, rigid and embedded foundations. In the low-frequency range, the translational, rocking and torsional components of the impedance matrix show clear effects of cross-interaction, which tend to disappear as the frequency and distance between the adjacent foundations increase. Regarding the foundation input motion associated with incoming SH-, P-, and SV-waves, the case of vertically propagating waves is very indicative of the cross-interaction effects. With respect to each other, the two foundations present displacement and rotational components that are either in phase or  $180^\circ$  out-of-phase while, with respect to the free-field soil, they move with a phase shift that varies with frequency. By increasing the distance between the two foundations, each component of the foundation input motion approaches the corresponding one for the case of an isolated foundation. In the horizontal direction, the displacements of the second foundations are 10% lower than the value of the

first footing and the two foundations move completely out of phase with respect to each other and to the free field soil. For waves propagating with angles of inclination in both planes, vertical and horizontal, the motion of the two foundations becomes more complicated, showing differences in both amplitude and phase [19].

## 2 DEFINITION OF THE SOIL-FOUNDATION IMPEDANCE

Impedance functions represent the frequency-dependent stiffness and damping characteristics of the foundation-soil system, which link the forces acting on the foundation to its displacements. The typical expression of an impedance function is:

$$S_{ij}(\omega) = \bar{K}_{ij}(\omega) + i\omega\bar{C}_{tot,ij}(\omega) \quad (1)$$

with  $i = j = x, y, z$  for the translational motion along the three principal axes;  $i=t$  and without the  $j$ -term for the rotation around  $z$  (torsional mode) and  $i=r$  and  $j=x$  or  $y$  for the rotation around the  $x$  or  $y$  axes. The dynamic stiffness  $\bar{K}_{ij}$  is the product of the static stiffness  $K_{ij}$  and the dynamic stiffness coefficient  $k(\omega)_{ij}$ , while the total damping  $\bar{C}_{tot,ij}$  is the sum of a contribution related to the soil hysteretic damping ratio  $\beta$  and to the radiation damping. This latter is due to the waves scattering from the foundation and is the product of a static value  $C_{rad,ij}$  and a dynamic coefficient  $c_{rad,ij}(\omega)$ .

$$\bar{K}_{ij} = K_{ij} \cdot k(\omega)_{ij} \quad (2)$$

$$\bar{C}_{tot,ij} = C_{rad,ij} \cdot c(\omega)_{rad,ij} + \frac{2\bar{K}_{ij}\beta}{\omega} \quad (3)$$

The value of each term depends on the angular frequency,  $\omega$ , as well as on the foundation shape and embedment. Classical solutions are provided by Gazetas (1991) [5], Pais and Kausel (1988) [1] and Mylonakis et al. (2006) [14] assuming a rigid arbitrary-shaped foundation placed on the surface of an ideal halfspace or embedded in it. Additional formulations are available in literature to account for the variation of the shear stiffness variation with depth (Gazetas, 1991[5]; Vrettos, 1999 [24]), foundation embedment (e.g., Apsel and Luco, 1987 [2]), and flexibility (e.g., Iguchi and Luco, 1982 [6]).

In the following, the second subscript  $x, y, z$  referred to the translational components of the impedances will be omitted for the sake of brevity.

### 2. Numerical analysis

This section illustrates the procedure used in the performed study for the evaluation of the impedance functions. Through a finite difference commercial code, a single footing was firstly modelled and the obtained impedances were compared to the closed-form solutions published in literature (Gazetas, 1991[5]). Later, another foundation with the same geometric and load characteristics of the master one was added. The impedances for the double footing system

were compared to the corresponding values of the single foundation case to appreciate the cross-interaction effects.

## 2.1 Details on the numerical model and load application procedure

The 3D analysis domain (Figure 1) is a soil volume with a square plan (80m on each side), and a height of 50 m. Both the single (a) and the double foundations (b) were considered rectangular with a base  $B$  equal to 2m and a length  $L$  of 10m. Three different values of spacing between the two footings were considered ( $S=2, 1$  and  $0.5$  m) so that the ratio  $S/B$  was varied between 0.25 and 1. In the static conditions, fixed boundaries were placed at the bottom and lateral surfaces delimitating the soil volume, while quiet boundaries were activated during the dynamic analyses to delete the reflection of the outward propagating waves and allow the necessary energy radiation towards infinity. As soil behaviour concerns, a linear visco-elastic isotropic law was assigned to all soil elements. Viscous damping was introduced in the model through the Rayleigh formulation. Soil damping was set to a very low value so that the overall damping encompassed in the numerical simulations can be assumed to be totally radiative. The presence of the groundwater was not considered, so the analyses were conducted in total stress. Table 1 shows the physical and mechanical properties assigned to the soil in the parametric analysis.

Material properties	Unit	Value
Soil unit weight $\gamma$	[kN/m <sup>3</sup> ]	19.0
Bulk modulus $K$	[Mpa]	12.2
Shear modulus $G$	[MPa]	5.6
Shear wave velocity $V_s$	[m/s]	54.0

**Table 1: Parameters assigned to the soil in the numerical study.**

Figure 1: Analysis domain (a), single foundation (b) and double foundation system (c).

The structural element of the footing was not included within the numerical model, but its effect was accounted by applying a velocity field at all nodes placed on the foundation footprint. Since a uniform displacement field was applied to these nodes, the case of a rigid foundation ( $EI \rightarrow \infty$ ) was hence reproduced. In the static case, a constant velocity along x-, y- or z-directions was applied to all grid points of the contact area in order to calculate the corresponding translational stiffness components. To obtain the rotational stiffness, nodal velocities varying with a linear distribution with respect to the x and y axes of the footing and null in correspondence of the centre of the foundation were imposed. In this way, the moment acting around each horizontal axis was simulated. In the dynamic case, a harmonic function of velocity [ $v(t) = \omega A \cos(\omega t)$ ] has been applied, so that the imposed displacement  $s(t)$  is harmonic too and given by:

$$s(t) = A \sin(\omega t) \quad (4)$$

where  $A$  is the oscillation amplitude and the circular frequency  $\omega$  is linked to frequency  $f$  by the well-known relation,  $\omega = 2\pi f$ . Different values of the input frequency  $f$  were considered that is 1, 3, 5, 7, 9, 11 and 13 Hz. By imposing the harmonic velocity time-history at all nodes of the loaded area, the induced stress state is also harmonic, with an amplitude depending on the soil stiffness and out of phase with respect to the displacement due to all damping sources present in the model.

## 2.2 Interpretation method

By calculating the resultant of the contact stresses, the static stiffness in the vertical direction was obtained as:

$$K_z = \frac{F}{\delta} = \frac{\sum_{i=1}^N \sigma_{zzi} A_i}{\delta} \quad (5)$$

where  $A_i$  represented the area of the mesh elements below the loaded footprint,  $\sigma_{zzi}$  the contact pressure at the  $i$ -th node of the loaded area and  $\delta$  the displacement at the footing centre. The values obtained numerically were compared to those provided by the available literature solutions (Gazetas, 1991). For the other translational degrees of freedom (d.o.f.) of the footing, the static stiffnesses were calculated with the same procedure described above for the vertical direction.

The rotational stiffness was calculated as the ratio between the moment,  $M$ , and the applied rotation,  $\theta$ :

$$K_{ry} = \frac{M}{\vartheta} = \frac{\sum_{i=1}^N \sigma_{zzi} y_i A_i}{\vartheta} \quad (6)$$

and

$$K_{rx} = \frac{M}{\vartheta} = \frac{\sum_{i=1}^N \sigma_{zzi} x_i A_i}{\vartheta} \quad (7)$$

The moment has been obtained through integration of the vertical stresses computed below the foundation footprint, multiplied by the distance from the rotation axis, i.e.  $y_i$  or  $x_i$ . The rotation has been obtained as ratio between the vertical displacement obtained at the edge of the foundation footprint and the half-length (in x and y direction) of the foundation itself.

To obtain the impedance functions in the frequency domain, the Fourier transforms of the displacement and of the force were required. Having imposed a given velocity (therefore, a displacement) and not a load, it was better to calculate firstly the soil-foundation flexibility (inverse of stiffness) and then the impedance matrix as the inverse of the flexibility. As it is well known, the dynamic stiffness and damping correspond to the real and the imaginary parts of the impedance.

### 3 RESULTS

#### 3.1 Static case

In Table 2, the static stiffnesses computed through the procedure described above have been compared to those provided by Gazetas (1991) [5] closed-form equations. In the last column of Table 2, the percentage of variation between numerical and analytical values for each d.o.f. are listed. The analytical values were obtained by considering a single strip footing placed on a homogeneous half space with the same parameters reported in Table 1. From Table 2, it can be observed that the obtained numerical predictions are in good agreement with the values provided by the literature formulations, especially for the vertical and rotational degrees of freedom. The higher mismatch may be observed on the translational mode along x and y directions.

	Numeric value calculated	Gazetas (1991)	Variation (%)
$K_z$ [N/m]	9.62E+07	9.85E+07	-2.33
$K_y$ [N/m]	6.47E+07	8.75E+07	-26.06
$K_x$ [N/m]	6.07E+07	7.69E+07	-21.07
$K_{ry}$ Nm/m]	1.38E+09	1.46E+09	-5.48
$K_{rx}$ Nm/m]	1.25E+08	1.28E+08	- 2.30

**Table 2: Comparison between the static stiffness obtained through the developed numerical procedure and solutions proposed by Gazetas (1991)**

Figure 2 shows the results obtained for the system of two identical footings placed at different distance  $S$  between them. On the vertical axis of both figures, there is the percentage of variation of the translational (a) and rotational (b) static stiffness of the master footing when considered as part of a group and when considered alone. Since this percentage for all swaying motions and rotational  $K_{ry}$  are negative, the static stiffness of the footing in a group, as expected, is always smaller than that of the same foundation considered isolated ( $K_{\text{double}} < K_{\text{single}}$ ). In addition, for all modes the static stiffness of the master footing in a group decreases with decreasing the ratio  $S/B$  due to cross interaction effects. Singular is the case of the rotational

stiffness  $K_{rx}$  (long side of the footing), which is always positive ( $K_{rx\_double} > K_{rx\_static}$ ) and seems poorly affected by cross interaction when  $S/B$  is equal to 0.25.

Figure 2: Static stiffness of the master foundation in group (double) or isolated (single) for the translational (a) and rotational (b) component of motion.

#### 4.2 Dynamic case

The variation of the dynamic coefficients against the dimensionless frequency  $a_0 = \omega B/V_s$  are plotted in the Figures 3-7 for different distance ratios,  $S/B$ . In addition, the impedances obtained numerically and analytically for the isolated footing have been superimposed for comparison.

For a single foundation, the obtained results (red line) are in excellent agreement with the analytical values (black line) provided by Gazetas (1991) equations up to a dimensionless frequency  $a_0$  equal to 1. For  $a_0 > 1$ , a slight mismatch is observed for the horizontal translational modes (Figures 4 and 5). Similar observations may be drawn for the radiation damping coefficients. The damping coefficients  $c_{rx}$  and  $c_{ry}$  (Figures 6 and 7), instead, are slightly higher than those obtained analytically in the whole range of dimensionless frequency  $a_0$ . In short, for the single footing the differences between the numerical and analytical predictions are quite small, so that the overall developed numerical procedure may be considered reliable.

With reference to the twin footing system, it can be observed that the impedances of the master foundation in the group are close to those of the single footing for low values of the frequency  $a_0$ . Conversely, there is a systematic increase of the stiffness coefficient for the footing in the group at higher frequencies, except for the rotational d.o.f. around the x-axis (long side in Figure 6). The dimensionless frequency at which the presence of an additional footing influences the results decreases with increasing  $S/B$ . Actually, the interference occurs when the wave originated from the clone foundation forces the master one to move out of phase with respect to its original motion. Such effect depends on the forcing frequency and on the  $S/B$  ratio. In fact, longer wavelengths, associated to lower frequencies, make closely-spaced foundations with smaller  $S/B$  (e.g.,  $S/B=0.25$ ) to move together without altering the response with respect to the isolated case. This means that closer are the foundations, higher is the frequency at which they interfere. No relevant differences may be recognized with changing the degree of freedom of the foundation.

The damping coefficients of the twin footing tend to increase with respect to that of the single foundation for the vertical motion (Figure 3) and this increase is proportional to  $S/B$ . Only for  $S/B=1$  there is a decrease starting from  $a_0=1$ , i. e. for a  $f=9$  Hz. The same trend is observed for the rotational d.o.f. around the y axis (Figure 7) and the opposite trend results for

the other translational components of motion (Figure 4 and 5). Such differences are associated to the fact that the wavefront originated by the twin footings interfere in a constructive or destructive way depending on the type of waves generated by the foundation motion.

Figure 3: Vertical dynamic stiffness coefficients (a) and damping coefficients (b).

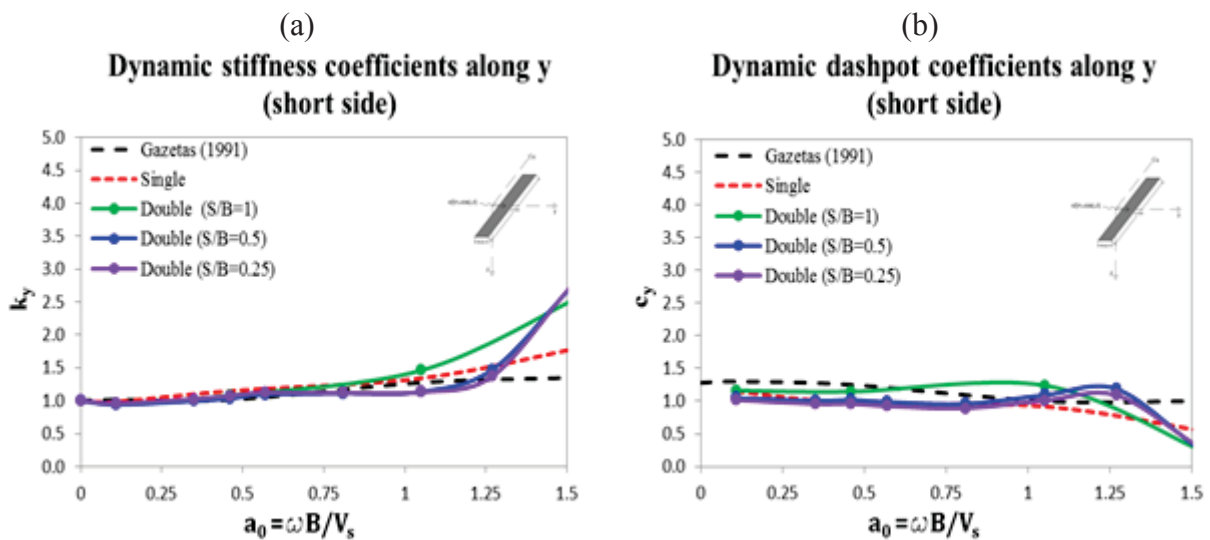

Figure 4: Horizontal dynamic stiffness coefficients (a) and damping coefficients (b) along short side.

Figure 5: Horizontal dynamic stiffness coefficients (a) and damping coefficients (b) along long side.

Figure 6: Rotational dynamic stiffness coefficients (a) and damping coefficient (b) around long side.

Figure 7: Rotational dynamic stiffness coefficients (a) and damping coefficients (b) around short side.

#### 4 CONCLUSIONS

The static and dynamic cross interaction between two closely-spaced shallow foundations was numerically investigated through a numerical procedure based on the finite difference technique. The cases of a single foundation and of two identical footings placed on the surface of a viscoelastic half-space were solved numerically.

For the single foundation case, the impedance functions thus obtained successfully reproduced those provided by Gazetas (1991) solutions.

For the twin foundation case, lower values of the static stiffness were found for almost all degrees of freedom due to cross-interaction effects. The dynamic stiffness coefficients were found coincident with those of the single foundation at low oscillation frequencies. Higher values were, instead, obtained for a typical dimensionless input frequency that markedly depends on footing-footing distance ratio  $S/B$ . The dynamic damping coefficients increase or decrease with respect to that of the single footing depending on the type of oscillation mode of the foundation. As a future perspective of the study, the current parametric study could be enriched with considering different configurations of the footing group, different values of soil damping, stiffness, foundation embedment and type of loading.

### Abstract

*The paper investigates the effects of site-amplification and soil-foundation-structure interaction (SFS) on the fragility curves of a real unreinforced masonry (URM) structure. The building is inspired to a school with an irregular T-shape plan and is modelled according to the equivalent frame approach. The structure was ideally placed on a stiff rock outcrop (case FB A) or settled on four different soft soil profiles, including its real foundation subsoil. In the latter cases the base of the structural model was assumed as fixed (FB C) or endowed with springs (CB C) simulating the soil-foundation dynamic impedance. To evaluate the fragility curves, the corresponding structural models were analysed through non-linear dynamic analyses under 136 input motions, propagated in 1D soil models reproducing the selected profiles for FB C and CB C. The results were compared in the paper in terms of:*

- fragility curves calculated for five damage levels (defined to be conceptually consistent with those of the EMS98 scale) and expressed as a function of different intensity measures of the input motion;*
- average damage derived as a weighted average of the probability of failure associated to all the damage levels.*

*The comparison among the results of the different models highlights the expected increase of damage due to site effects and a beneficial effect of soil-structure interaction, mainly due to the increment of damping associated to the additional energy dissipated by the soil-foundation system. Finally, the average damage of FB C and CB C models were compared with those obtained from the fragility curves of a fixed base system in which site effects are considered through the conventional coefficients proposed in Codes (e.g. by the Eurocode 8), that neglect SFS. This latter approach is that followed in the current practice. The comparison demonstrates that the Code-based approach underestimates the fragility especially at high damage levels.*

## 1 INTRODUCTION

Various reconnaissance studies after seismic events [1, 2, 3] as well as more specific studies at scale of whole historical centres [4, 5, 6] testified as the site-amplification effects (either associated to topographic and soil stratigraphic effects) may play a relevant role, together with their vulnerability, in determining the resulting damage levels on existing unreinforced (URM) masonry. The microzonation studies, developed in various area in Italy after the recent seismic events [7, 8] that hit the country, confirmed this potential risk factor.

Together with this evidence at large scale or on huge building stocks, studies based on detailed models of prototype buildings and more refined analyses methods turn out very useful to understand the phenomenon and also deepen the potential effect of the soil-foundation-structure interaction (SFS). In [9] the topic is treated in a parametric way to attempt in providing a general overview of such effects on various structural typologies (classifiable according to their dynamic behaviour as “stiff” or “flexible”) concluding how the SFS may produce either beneficial or detrimental effects. The literature works specifically addressed to URM buildings are still very few, and usually focused to slender structures, like as towers or minarets [10, 11, 12], or massive monumental assets, like as fortresses [13, 14]. A recent very interesting case, that testified the possible role of SFS also on ordinary URM buildings, is constituted by the “P. Capuzi” school in Visso (MC, Italy). Being monitored as a strategic building by the Italian Seismic Observatory of Structures [15], the school response under the three mainshocks of the 2016-2017 Central Italy earthquake was recorded through numerous accelerometers installed in the building as well as the damage after each event was detected through on-site inspections. Although nowadays the school has been demolished due to the very severe damage occurred, all the precious data collected were very useful to validate numerical models and assess the role played by SFS phenomena in the seismic response of the school, like by [16, 17].

In particular, in [16] a compliant-base model has been successfully validated thanks to these data. This model, that works according to the equivalent frame modelling approach, is the one adopted also for the further developments presented in this paper, which focuses to both the site-amplification due to soil stratigraphic effects and the role played by SFS.

More specifically, the numerical strategy validated in [16] thanks to the actual recordings from the 2016-2017 Central Italy earthquake has been replicated by executing a huge set of nonlinear dynamic analyses (NLDA) with the final aim of developing fragility curves, similarly to what done for example by [5, 18, 19]. The model (briefly recalled at §2.3) has been analysed both as fixed at the base (FB) and endowed with springs (CB) simulating the soil-foundation dynamic impedance. NLDA have been performed according to the Cloud Method (see e.g. [20]) with a selection of records extracted from the SIMBAD database in [21, 22] to be representative of real events recorded on stiff rock outcrop. Then, they have been propagated by considering four different soft soil profiles (§2.1) representative of a class soil C (according to classification adopted in [23, 24]), including the real foundation subsoil of the school (§2.2). Fragility curves are defined assuming a log-normal distribution. The structural response from NLDA is interpreted according to a multiscale approach briefly described at §2, that allows to attribute to each records a damage level, defined to be conceptually consistent with those of the EMS98 scale [25]. Moreover, different intensity measures of the input motion have been considered in order to assess the sensitivity to the dispersion in the definition of the fragility curves (§3.1), namely the Peak Ground Acceleration (PGA) and the Spectral Acceleration corresponding to the fundamental period of the structure ( $S_a(T_1)$ ).

Finally, the average damage of FB C and CB C models were compared with those obtained from the fragility curves of a fixed base system in which site effects are considered in a simplified way through the conventional coefficients proposed in Codes (e.g. by the Eurocode 8 [24]),

that neglect SFS (§3.2). This latter approach is that followed in the current practice. The comparison aims to assess if the current Code-based approach is on the safe side or not, also varying the expected damage level (i.e. the nonlinear phase attained by the structure).

## 2 METHOD OF ANALYSIS

As introduced at §1, in this study fragility curves of a URM building endowed with shallow foundations were calculated accounting for both the amplification of the ground motion due to site effects and the dynamic soil-foundation-structure (SFS) interaction. Due to the low foundation embedment, the foundation input motion is expected to be equal to the free field motion, hence the latter was calculated through linear-equivalent one-dimensional site response analyses performed on four soil profiles. The resulting ground motion (illustrated at §2.3) was then used as input motion to perform non-linear dynamic analyses on:

- a fixed base structural model (indicated as FB C in the following);
- a compliant base structural model in which the base of each main wall is equipped with springs (indicated as CB C in the following).

The rich and huge amount of data from each nonlinear dynamic analysis carried out are interpreted according to a multiscale approach with the final aim of interpreting the simulated structural response through a synthetic parameter consisting in the global damage level. The latter has been defined to be conceptually consistent with the five ones defined in the EMS98 scale [25], that is (DL<sub>i</sub>,  $i=0\dots5$ ): DL0 - none; DL1 - negligible; DL2 - moderate; DL3 - severe; DL4 - very severe to near collapse; DL5 - collapse. In particular, the adopted multiscale approach, similarly to what originally proposed in [26], combines two heuristic criteria:

- a first one that directly refers to the global response scale, by defining proper thresholds of the displacement capacity of the building on pushover curves estimated from nonlinear static analyses. These thresholds are defined in terms of proper fractions of the overall base shear ( $V_b$ ): before the attainment of the maximum value ( $V_{b,max}$ ) to define the DL1 (equal to  $0.4 V_{b,max}$ ) and DL2 (equal to  $0.8 V_{b,max}$ ); after the attainment of the maximum value, i.e. on the softening phase of the curve, to define the DL3 (corresponding to a residual capacity equal to  $0.8 V_{b,max}$ ), DL4 (corresponding to a residual capacity equal to  $0.4 V_{b,max}$ ) and DL5 (corresponding to a residual capacity equal to  $0.2 V_{b,max}$ ).
- a second, based on the evaluation of damage severity and diffusion on vertical walls, that aims to monitor the spread of damage on the building. To this aim, the cumulative rate of walls that reached a given DL (graduated on five level) is computed. The attainment of the DL on a wall is checked in terms of the  $DL_{min}$  variable firstly introduced in [27]. This variable replaces the adoption of interstorey drift thresholds at the wall scale and the proposal assigns a damage level to the wall based on the minimum damage level attained by all the elements of a certain floor. This allows overcoming the definition of conventional interstorey drift thresholds, which are not suited to take into account the different damage mechanism exhibited by structural elements of different slenderness. A similar damage-assignment criterion has been recently pursued in Italian Structural Code [28]. The thresholds assumed for the cumulative rate have been defined to be consistent with the linguistic description of the damage grades of buildings proposed by the European Macroseismic Scale [25]; they are described in more detail in [29, 30].

According to this procedure, results of records can be properly grouped as those associated to the same resulting global DL.

Then, fragility curves were computed by estimating the probability of exceeding,  $p_{DLi}$ , the different damage levels, DL<sub>i</sub>, given a level of ground shaking quantified through the intensity

measure,  $IM$ . The  $p_{DLi}$  was computed from the lognormal distribution of  $IM$  causing the  $i^{th}$  DL and characterized by the median value  $IM_{mi}$  and the lognormal standard deviation  $\sigma$ .

$$p_{DLi}(DL > DLi|IM) = \Phi\left(\frac{\log IM|IM_{mi}}{\sigma}\right) \quad (1)$$

Where  $\Phi$  is the standard cumulative probability function.

Among possible intensity measures [31], in this study, the peak ground acceleration, PGA, and the spectral acceleration,  $Sa(T_1)$  referred to the bedrock input motion were used as  $IM$ . This choice is consistent with various studies on URM buildings [32, 33, 34]. In particular, the geometrical mean of the PGA and the  $Sa(T_1)$  associated to the predominant period along the X and Y directions of the numerical model was used. Since an elongation of the periods is expected for the compliant base models, the  $Sa(T_1)$  of the CB C case differs from those of the FB C case, while the PGA is obviously the same for the two models.

On basis of this procedure, the fragility curves resulting from the FB C model account only for site effects, while those of the CB C model consider both the site and SFS effects. Both cases have been then compared with the fragility curves of the same structure ideally placed on a stiff rock outcrop. The latter were obtained by analyzing the behavior of the fixed-base model subjected to the input motions representative of the bedrock condition (namely the FB A case in the following).

## 2.1 Analysed soil profiles

To study the influence of the soil stiffness on the results of FB C and CB C cases, four soil profiles were selected. The criterion adopted for the selection is that based on an equivalent shear wave velocity up to the bedrock depth,  $V_{seq}$ , falling in the range of class C (as defined by [23, 24]). The first profile (S1) is the actual soil below the “P. Capuzi” School of Visso, i.e. a sandy gravel layer (SG), covered and locally interbedded by clayey silt (CS) and silty clay (SC) lenses. The stiffness profile was measured through a MASW test [35] and several down-hole tests [36]. The on-site measured free field frequency obtained from HVSr tests allowed the back-calculation of the bedrock depth equal to 40 m. The shear wave velocity,  $V_s$ , is variable with depth with an equivalent value up to the bedrock equal to 281 m/s. Additional details on the geotechnical characterization of this soil profiles are reported in [16].

The second profile (S2) is the actual soil in the historic centre of Visso, investigated through two boreholes and a HVSr test [36]. The profile is made of clayey silt (CS) for the first 4 m, overlaying a 11 m thick sandy gravel layer (SG). The geological section of the Visso valley reported by [36] individuates the bedrock at a depth of 18 m. In lack of a direct measure of  $V_s$ , its value was obtained through a correlations law between  $V_s$  and the number of blows of SPT tests performed at a depth of 1.9 m in CS and 4.4 and 8.9 m in SG, respectively. Before the application, numerous correlation law available in the literature were checked against the results of down hole tests in the same valley. Such validation is not reported here for sake of brevity. The most successful correlations in the validation were used to characterize S2. In particular, the correlations by [37, 38] were used for CS, leading to the same  $V_s=162$  m/s, and by [39] for SG, leading to  $V_s=337$  m/s. The consequent equivalent  $V_s$  up to the bedrock depth is  $V_{seq}=272$  m/s. Finally, two other ideal clay (S3) and gravel (S4) profiles were considered with the bedrock placed at a depth of 40 m. In both cases  $V_s$  increases with depth. Its profile was calculated through the empirical laws by [40] for S3 and by [41] for S4, respectively. The resulting  $V_{seq}$  are 200 and 279 m/s, which are similar to those of S1 and S2.

Figure 1a summarizes the four soil and  $V_s$  profiles while Figure 1b reports their amplification functions. The latter have been calculated through a linear site response analysis performed by

using the STRATA software [42]. As highlighted by the resulting natural frequencies, there is a significant variety among the responses of the different soil profiles.

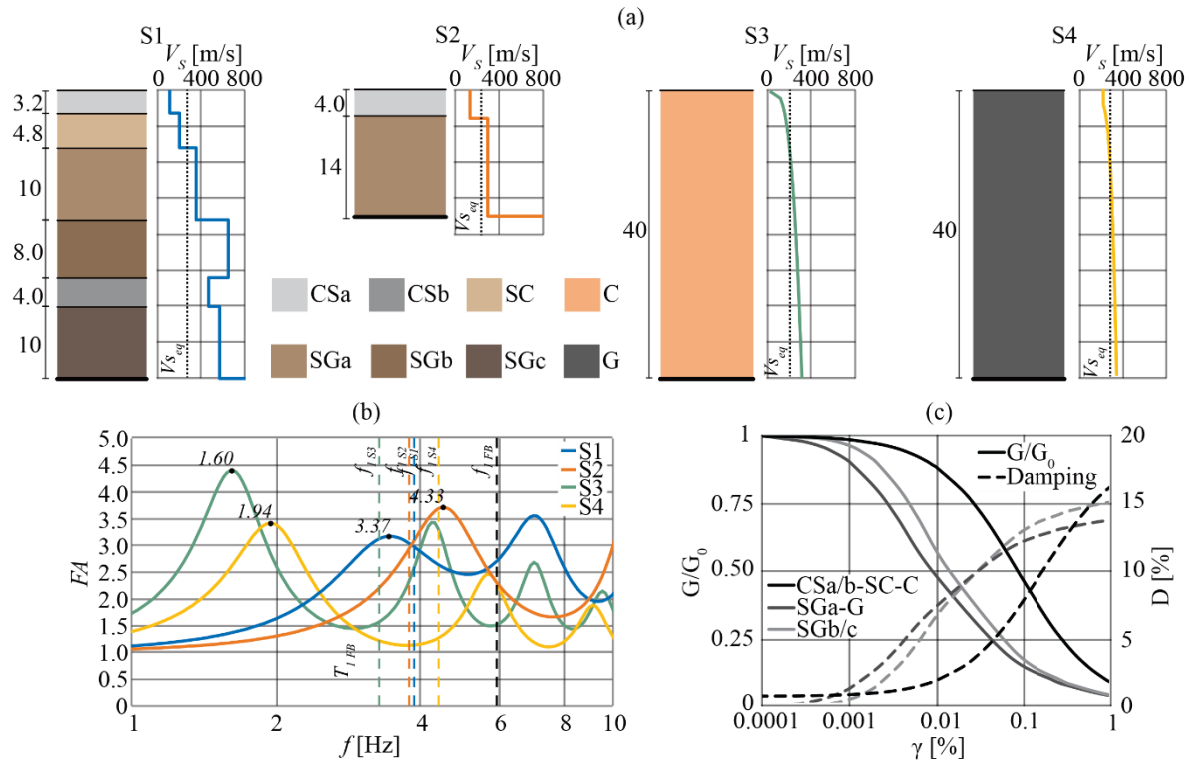

Figure 1: (a) layer with profile  $V_s$ ; (b) FA of the four stratigraphies and (c) decay curves of the soils considered.

Finally, Figure 1c shows the variation of the normalized shear modulus ( $G/G_0$ ) and the damping ratio ( $D$ ) with the shear strain ( $\gamma$ ) adopted in the linear equivalent site response analyses executed with the records of real earthquakes and performed again in the STRATA software. The curves adopted for the fine-grained soils in S1, S2 and S3 were obtained based on a comprehensive model calibrated by [43, 44] on the results of laboratory tests on comparable materials. The  $G/G_0$ - $\gamma$  curves obtained by [45], through laboratory tests on silty sandy gravel samples different confining stress were associated to the sandy gravel soil in S1, S2 and S4. The corresponding  $D$ - $\gamma$  curves were calculated by applying the model by [46] and the Masing criteria [47] to the  $G/G_0$ - $\gamma$  curves.

## 2.2 Results of site response analyses under records of real earthquakes

Figure 2 shows the acceleration time histories of the input motions employed to analyse the site effects in the four soil profiles described in §2.1. They were chosen from the Selected Input Motions for Displacement-Based Assessment and Design (SIMBAD) database [21, 22].

The selection includes the EW (Channel 1 (C1)) and NS (Channel 2 (C2)) components of accelerations recorded during 49 natural events at stations located on stiff rock outcrop, *i.e.*  $V_{s30}$  greater than 700 m/s. Some selected signals were slightly scaled to achieve the desired variability of the intensity measures to be used in the construction of the fragility curves of the FB A.

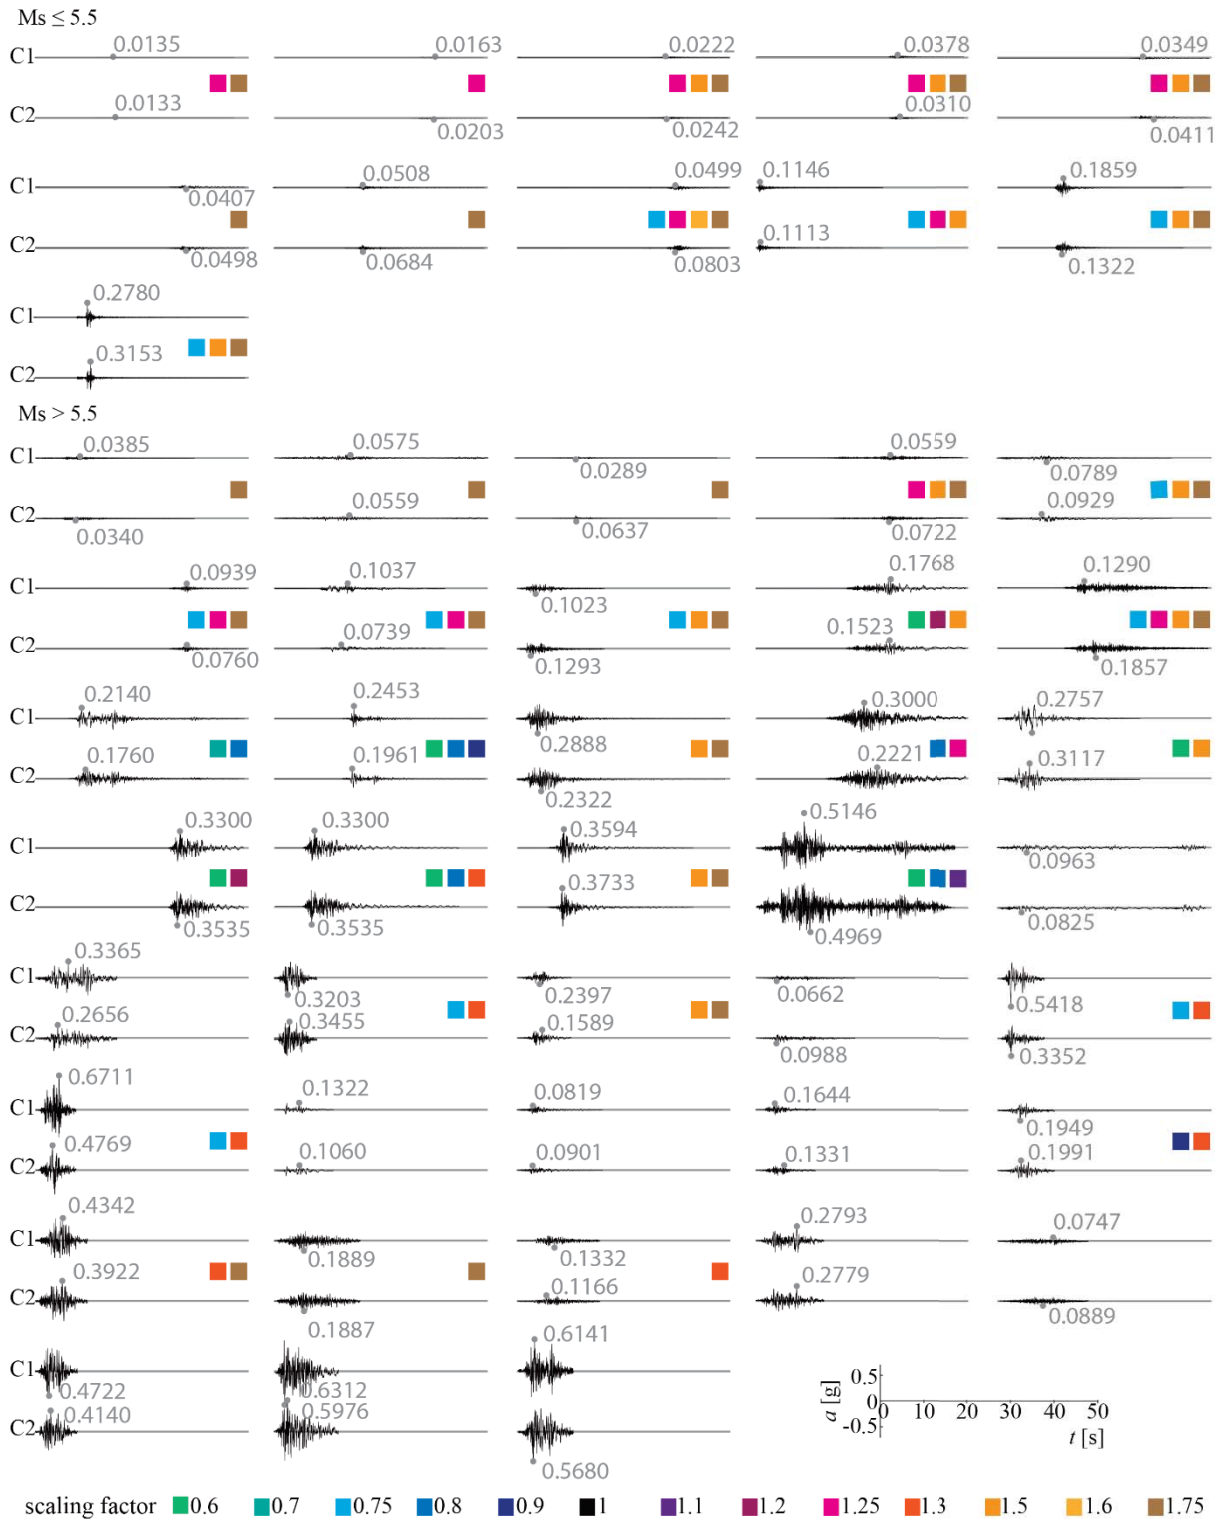

Figure 2: Time histories of the acceleration of the selected input motions.

Colours in Figure 2 indicate the scaling factors, when multiple colours are present, the same input motion was scaled more than once.

Figure 3 shows the mobilized  $G/G_0$  (a) and hysteretic damping ratio (b) calculated in the four considered soil profiles through site response analyses under each event. The mean values

mobilized in the soil volume, expected to be affected by the foundation motion (i.e. 1 m under foundation level) are reported. As expected, the highest effects of nonlinearity are recognized: for the profile S3, characterized by the lowest initial stiffness; and the gravel soil profile S4, characterized by the earliest development of stiffness reduction (see Figure 1c). Conversely the lowest nonlinearity corresponds to the shallowest bedrock producing the highest natural frequency, *i.e.* the stiffest response (see Figure 1b). The actual soil profile below the school, S1, shows an intermediate behaviour.

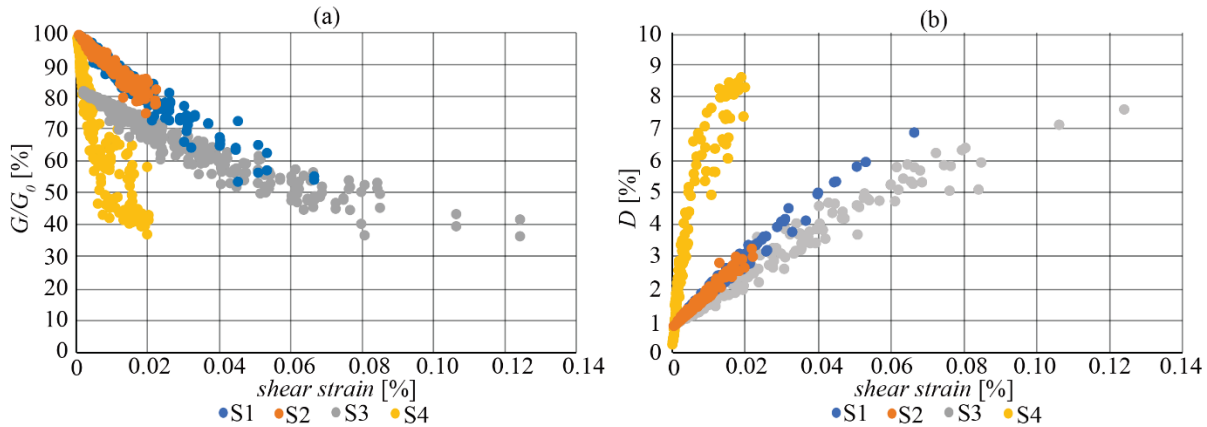

Figure 3: (a)  $G/G_0$  and (b) hysteretic damping ratio mobilized in the four soil profiles in significant volume during each site response analysis.

Figure 4 groups the analyses according to different ranges of  $Sa(T_1)$  of the free field motion resulting from the site response analyses and corresponding to the fixed-base period. The latter are reported in Table 1 together with the period of the CB models on the different soil profile, revealing that the different initial shear stiffness of the soil profiles significantly affects the CB C period.

Model	FB	CB -S1	CB -S2	CB -S3	CB -S4
$T_1$ [s]	0.1740	0.2580	0.2640	0.3050	0.2298

Table 1: first period of each model.

The comparison among the number of signals belonging to each group, reported in red on the top of Figure 4, shows that  $Sa(T_1)$  values on surface of profile S4 are lower than 1.5 g and mainly concentrated in the lowest amplitude ranges. The ranges associated with the highest  $Sa(T_1)$  are populated mainly by signals propagated in S1 and S3, highlighting that such profiles are more hazardous for the structural safety.

In the same Figure 4 the number of times in which  $Sa(T_1)$  of the CB models exceeds that of the FB ones is reported in percentage on the Y-axis. Except for S2 showing a more irregular trend, such percentage increases with increasing  $Sa(T_1)$  and is predominant (*i.e.* >50%) from  $Sa(T_1) > 0.75$  g. Hence, a detrimental effect of SFSI is shown on the seismic actions affecting the structure especially under the most severe input motions.

Figure 4: number of times in which  $Sa(T_1)$  of the CB model exceeds that of the FB.

### 2.3 Numerical model of the selected URM building

The 3D model of Visso school (Figure 5a) adopted for the execution of NLDA works according to the equivalent frame (EF) approach. It has been realized with the Tremuri software package [48] and has been calibrated in [16] thanks to the available data on the structure from the permanent monitoring and previous studies [35]. The choice of adopting the EF model is justified by the regular pattern of openings in walls and by the evidence from the actual seismic response [49], that clearly highlighted the concentration of cracks in specific portions of the walls (namely, the piers and spandrels, respectively identified in orange and green in Figure 5a). The constitutive law used allows for describing the nonlinear response until very severe damage levels at element scale (i.e.  $DL_E$  from 1 to 5) through progressive strength degradation corresponding to assigned drift values; with the aim of executing NLDA [34], the constitutive law includes also a hysteretic response (Figure 5b). The latter is based on a phenomenological approach that allows also to differentiate the hysteresis loops in spandrels and piers and also varying the prevailing failure mode (e.g. if dominated by the flexural response or diagonal shear cracking). For further details on mechanical panel properties and modelling assumptions the interested reader may refer to [16].

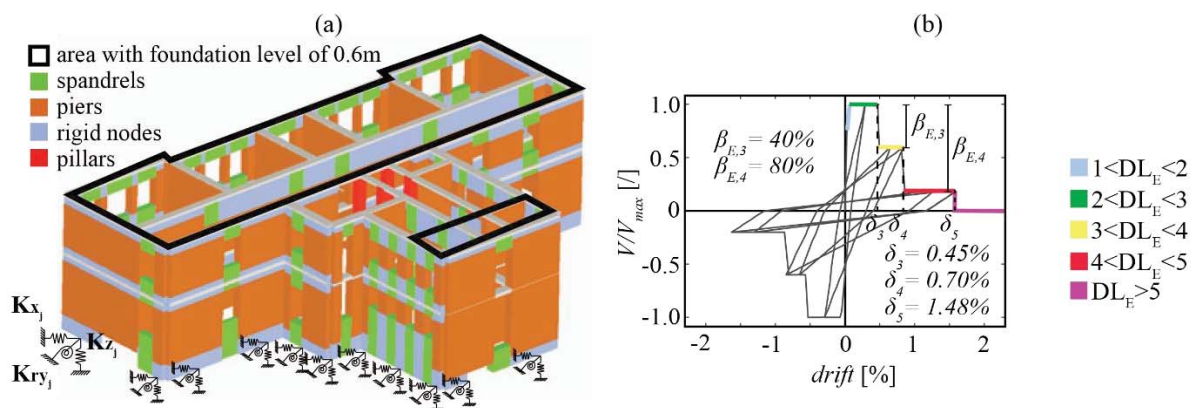

Figure 5: (a) 3D equivalent frame model with springs implemented in the CB model, (b) backbone and hysteretic response of masonry elements: piers under shear.

To simulate the base compliance, each foundation pier was equipped with springs (see Figure 5a), which stiffness was calibrated through the real part of the soil-foundation impedances by [50]. The foundation width was set equal to 0.90 m, while its length was defined by adding the

half-length of the spandrel panel to the size of the load-bearing wall. The value of the embedment was set to 0.6 m, except for the area indicated in Figure 5a, where the embedment increases up to 2.95 m due to the presence of an underground level. The soil was modelled as an equivalent linear half-space with a shear modulus equal to that mobilized at the foundation depth under each input motion. A full soil-foundation contact was assumed.

Firstly, the periods along the X and Y directions ( $T_x^*$  and  $T_y^*$ ) and the damping ratio ( $\beta_x$  and  $\beta_y$ ) of the SFS system were estimated through the replacement oscillator by [51]. To this aim, the building was approximated through a SDOF system with a viscous damping ratio equal to 3% and a lateral stiffness derived from the fundamental periods along the X and Y directions of the fixed base configuration (see [16]). To apply the formula by [51], the real and the imaginary parts of the monolithic foundation equivalent to the actual foundation systems were calculated from the sum of the real or imaginary parts of the impedances of the X-oriented (or Y-oriented) load-bearing walls. The contribution of the soil hysteretic damping mobilized at the foundation level (see Figure 3b) was added to the energy loss coefficients simulating the radiation damping ratio.

Then the frequency-dependent dynamic coefficients of the impedances were computed as a function of the resulting  $T_x^*$  and  $T_y^*$ , through an iterative procedure. To simulate the additional energy dissipation due to SFS interaction, the mean value of  $\beta_x$  and  $\beta_y$  was introduced as a Rayleigh damping ratio into the EF model. The calculation was repeated for each input motion: consequently, the impedances and the resulting  $T_x^*$  and  $T_y^*$  as well as the mean value of  $\beta_x$  and  $\beta_y$ , were updated according to the mobilized soil shear stiffness and damping ratio during each seismic response analysis (see Figure 3).

### 3 DESCRIPTION OF RESULTS

#### 3.1 Influence of site effects and SSI on the fragility curves

Table 2 reports the number of analyses (N), the median value  $IM_{50}$  (in acceleration unit g) and the standard deviation ( $\sigma$ ) used to generate the fragility curves of the fixed-base model analysed under the selected input motion (FB A).

Only few analyses, reported in brackets in Table 2, mobilize DL3, DL4 and DL5 for the FB A case; so the initial set of input motions described in Section 1.2 was integrated with the natural signals recorded on stiff soil and collected by [52]. However, the  $IM_{50}$  and  $\sigma$  resulting from the updated set of input motions are comparable with those obtained from the original selection (in brackets). There is only an increase, less than 10%, of the  $IM_{50}$  associated with DL5 in the case of PGA which results in a reduction of structural fragility.

	FB A				
	PGA		Sa( $T_1$ )		N
	$IM_{50}$	$\sigma$	$IM_{50}$	$\sigma$	
DL1	0.095	0.495	0.178	0.473	127
DL2	0.274	0.314	0.656	0.391	92
DL3	0.450 (0.413)	0.219 (0.255)	1.013 (0.969)	0.376 (0.423)	18 (10)
DL4	0.530 (0.488)	0.191 (0.147)	1.182 (1.156)	0.308 (0.299)	17 (7)
DL5	0.619 (0.562)	0.219 (0.178)	1.500 (1.428)	0.261 (0.314)	44 (12)

Table 2: Median value ( $IM_{50}$ ) and standard deviation ( $\sigma$ ) associated with to the various damage levels for the FB A model.

It is worth to remember that the IMs calculated for FB C and CB C refer to the bedrock. This implies that the  $IM_{50}$  values reduce moving from the FB A to FB C, independently of the soil profile. That highlights the expected increase of fragility for a fixed-base structure settled on soil type C with respect to that placed on soil type A, as shown in Figure 6 by way of example in the case of DL3.

Figure 6: Comparisons between the curves obtained from the FB A, FB C and CB C assuming PGA and  $Sa(T_1)$  as IM in case of DL3.

The comparison with the CB C models reveals an increase of  $IM_{50}$  with respect to the FB C case. Such modification reduces the probability of failure on the building. Since the elongation of the CB C period produces an increment of the seismic actions with respect to the FB C case (see Figure 4 and Section 2.2), such beneficial effect is mainly due to the increase of damping ratio produced by the SFS interaction, as shown in Figure 6 by way of example for DL3. This general conclusion is however extendable to all DLs.

The same beneficial effect is evident by comparing the number of analyses that fall into the various  $DL_i$  for the FB C and CB C. There is in fact a reduction of the analyses in the more severe DLs for the CB C model, in particular for the profile S4 where the analyses in DL5 are only 3. Such reduced number of analyses reduces the reliability of the DL5 fragility curve for S4, hence this case will not be considered in the following interpretations. Obviously, the reliability of DL5 would have been improved by scaling through higher factors the signals originally selected, but such procedure would have led to unrealistically strong free field motions. Conversely, the low occurrence of DL5 for S4 (resulting from the numerical analyses) appeared much more realistic, because buildings settled on gravel are less prone to high damage since they are affected by lower seismic actions (see Figure 4) and benefit of higher soil damping.

The estimation of  $p_{DLi}$  through Equation 2 allows the computation of the mean damage  $\mu_d$  expected to affect the structure, as follows:

$$\mu_d = \sum_{i=0}^5 (p_{DLi} i) \quad (2)$$

where  $p_{DLi}$  is weighted by  $i=0,1,2,3,4$  or 5 passing from DL0 to DL5.

The calculation was performed by entering the curves of the case FB C and CB C with the values of PGA and  $Sa(T_1)$ , at the bedrock of each selected input motion. The  $\mu_d$  value may be conveniently converted into an equivalent discrete damage level by assuming a binominal

distribution, leading to the following conversion intervals: 0-0.7 for DL0; 0.7-1.6 for DL1; 1.6-2.5 for DL2; 2.5-3.4 for DL3; 3.4-4.3 for DL4; 4.3-5 for DL5. The latter ones have been used to define the “square metric” in Figure 7. These comparisons are reported considering as IM: the PGA in (a); and the  $Sa(T_1)$  in (b). The grey fillings indicate a difference of 1, 2 or 3 DLs between the mean damage of FB C and CB C. In the case of the PGA, SFS interaction always leads to a reduction of the expected damage, independently of the soil profile and the greatest beneficial effects at DL3-4, specially for S3. Considering the  $Sa(T_1)$ , the results are more dispersed. In any case there is a greater damage associated with the FB C model, but there are also some cases in which the CB C model leads to greater damage, specially at lowest DL in S1 and S2. In this case, it is worth to remind that also the IM changes among the models, because the fundamental period changes as shown in Table 1.

Despite these slight differences, the general conclusion on the SFS effects observed from the use of PGA and  $Sa(T_1)$  is the same.

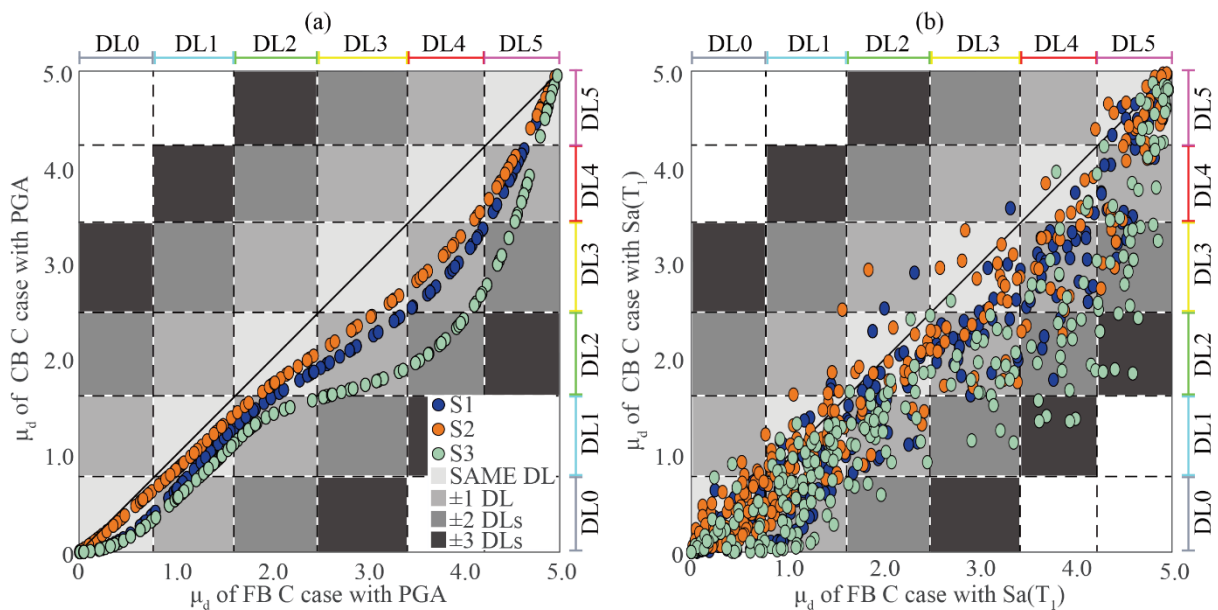

Figure 7:  $\mu_d$  between FB C and CB C for S1, S2 and S3 in case of (a) PGA and (b)  $Sa(T_1)$ .

### 3.2 Comparisons with the Eurocode previsions

In the most widespread cases of fragility curves generated for fixed base structures and stiff soil conditions (case FB A), site effects can be considered in the estimation of  $p_{DLi}$  in a simplified way, *i.e.* by entering in the curve with the IM amplified by the stratigraphic coefficient provided by Code. As an example, on the abscissa, Figure 8 shows the  $\mu_d$  resulting from the fragility curve of FB A in which the terms  $p_{DLi}$  in Equation 2 alternatively corresponds to peak ground (PGA\*) or the spectral ( $Sa(T_1)$ \*) accelerations, amplified according to the coefficient proposed by the [24]. This is equal to 1.5 for events with a surface wave magnitude lower than 5.5; otherwise it is equal to 1.15 (see Figure 2). When only site effects are considered (FB C) (see Figure 8a and b), EC8 underestimates the damage in any case and up to three damage levels. Soil-structure interaction reduces the gap between the  $\mu_d$  estimated through the Code conforming approaches and that estimated by explicitly accounting for the site effects joint to the soil structure interaction (CB C) (see Figure 8c and d). However, a difference of one DL (very rarely of two DLs) still results also for CB C. Such underestimation arguably would increase if the increment of damping ratio induced by SFS interaction was considered in the computation of the IM\*.

Figure 8: Comparison among the  $\mu_d$  resulting for the different analyzed cases from the curves expressed as a function of (a) PGA and (b)  $Sa(T_1)$  for FB C model, (c) and (d) for CB C model. In the FB A case, the  $PGA^*$  and  $Sa(T_1)^*$  values - amplified according to the coefficients proposed in the Eurocode 8 ([24]) - were used.

#### 4 CONCLUSIONS

The paper compares the fragility curves and the derived mean damages of a real URM structure ideally placed on stiff rock (FB A) or settled on four different soil profiles. The latter ones include its real foundation subsoil as well as other three with an equivalent shear wave velocity falling in the range of soil type C. The base of the structural model is alternatively assumed as fixed (FB C) or endowed with springs (CB C), simulating in that way the soil-foundation dynamic impedance.

The comparison among the results of the FB A and FB C cases shows the expected increase of the probability of failure when site amplifications are considered.

The comparison among FB C and CB C highlights: i) a general increase in the spectral accelerations affecting the model on springs; ii) a reduction of the probability of failure. As expected, the first effect (i) is due to the period elongation induced by the soil-foundation-structure interaction while the second (ii) is mainly ascribable to the increment of damping associated to the additional energy dissipated by the soil-foundation system.

The comparison among the results of models on the different soil profiles reveals that the highest damage levels are rarely achieved by structures placed on gravel. This is because they are affected by lower seismic actions and benefit of higher soil damping mobilized by the early development of nonlinearity in such soil types. Significant beneficial effects are also recognized for structures settled on soft clay again due to the significant damping mobilized by the considerable strain levels achieved in such profile.

Finally, the mean damages of FB C and CB C were compared with the values resulting from the probability of failures estimated by amplifying the intensity measure through the conventional coefficients proposed by Eurocode [24] to account for the site effects. The comparison shows that such simplified approach underestimates the damage up to two damage levels. Nevertheless, it is currently the most widespread procedure because fragility curves are mostly generated for fixed base structures and without considering site effects through site response analyses. Results achieved could be further developed in future works to improve also practice-oriented procedures.

### Abstract

*A simple, yet powerful analytical model for determining the dynamic response of laterally loaded piles has recently been proposed in a series of papers by Karatzia and Mylonakis. The method is essentially a finite-element formulation, based on the evaluation of a set of energy integrals to establish the dynamic stiffness and damping matrices at the pile head. The key ideas/assumptions behind the method are: (1) the soil around the pile is replaced by a bed of dynamic Winkler springs and dashpots accounting for soil stiffness and energy dissipation; (2) a shape function for pile deflection is employed along the whole pile length in each vibration mode; (3) the associated integrals can be solved in closed form. Solutions have been obtained for different soil profiles which provided realistic predictions of pile response to flexural loads. An implicit assumption of the method lies in the use of real-valued shape functions. While such functions greatly simplify the analysis by separating real and imaginary parts (thus leading exclusively to real-valued integrals), they have the disadvantage of ignoring the phase differences between pile movements at different depths.*

*This paper recognises that this simplification can lead to inaccurate results for inhomogeneous soil profiles, especially at high frequencies where phase differences among different points along the pile are significant. To overcome the problem, the possibility of using complex-valued shape functions, analogous to those employed in spectral finite-element methods is explored. It is shown, through comparison with rigorous numerical solutions (including FEM and BEM), that use of complex-valued shape functions improves the predictive power of the method.*

## 1 INTRODUCTION

Winkler based models are well established for use in elastodynamic analysis of laterally loaded piles. Early work provided analytical expressions for the spring and dashpot coefficients based on a horizontal soil “slice” model [1, 2, 3]. Several subsequent studies provided solutions for pile stiffness and damping in homogeneous and inhomogeneous media, as well as kinematic response coefficients to seismic excitation [4, 5, 6, 8, 9, 10, 11, 12, 15, 16, 25, 26, 27]. A difficulty in employing such solutions in design lies in the inability to derive exact solutions for inhomogeneous media in the dynamic regime. An alternative approach is explored in this paper, by means of an energy formulation analogous to those used in finite-element methods, based on single shape function for the whole pile length. The method was introduced in pile dynamics by Dobry and Roesset [6] and later extended in a series of papers by Mylonakis and co-workers [8, 9, 10, 11, 16, 26]. The main assumptions of the method are: (1) the soil around and under the pile can be replaced by a bed of dynamic springs and dashpots accounting for soil stiffness and pile-soil energy dissipation (Winkler approximation); (2) a single shape function can be employed for the deflection of the whole pile for each vibration mode (Rayleigh approximation); (3) a virtual work formulation can be employed in which the associated one-dimensional integrals can be evaluated in closed form. In this way, the three-dimensional elastodynamic problem reduces to a handful of one-dimensional integrals which can be evaluated in closed form for different inhomogeneous soil media. The solutions have been shown to provide realistic predictions of pile response to flexural loads.

A simplification associated with the above method lies in the use of real-valued shape functions for pile deflection. While such functions greatly simplify the complex arithmetic by separating real and imaginary parts leading to exclusively real-valued integrals, they have the disadvantage of ignoring the phase differences between pile displacements at different depths. This paper recognises that this simplification can lead to inaccurate results for inhomogeneous soil profiles, especially at high frequencies where the phase differences between displacements at different elevations along the pile are significant. To overcome the problem, the possibility of using complex-valued shape functions, analogous to those employed in spectral finite element methods, is explored in this paper.

## 2 PROBLEM DEFINITION

Figure 1: The dynamic Winkler model for a laterally loaded pile.

The dynamic Winkler model under consideration is shown in Figure 1. The pile is modelled as elastic Euler-Bernoulli beam with length,  $L$ , diameter,  $D$ , cross sectional area,  $A$ , second moment of area,  $I$ , mass density,  $\rho_p$ , elastic stiffness,  $E_p$  and hysteretic material damping coefficient,  $\beta_p$ . The last two terms can be expressed as a complex viscoelastic stiffness,  $E_p^* = E_p(1 + 2i\beta_p)$ .

A harmonic head load,  $P$ , and/or (anticlockwise positive) moment,  $M$ , are applied at an angular frequency,  $\omega$ , to the pile head. This is resisted by distributed Winkler springs and dashpots with coefficients  $k(z)$  and  $c(z)$ , respectively, which are often expressed as a complex-valued stiffness,  $k^* = k + i\omega c$ . The resulting pile displacement,  $y^*(z)$ , is also complex-valued, indicating a depth-varying phase difference from the applied load.

The governing equation describing the problem is obtained from the well-known expression for a beam under a distributed load [4]:

$$E_p^* I y^{*''''}(z) + [k(z) + i\omega c(z) - \rho_p A \omega^2] y^*(z) = 0 \quad (1)$$

where  $y^{*''''}(z)$  indicates the fourth derivative of  $y^*(z)$  with respect to depth,  $z$ .

Of most interest is the response at the pile head, which can be described using a complex-valued stiffness matrix,  $\mathbf{K}^*$ , defined as:

$$\mathbf{P} = \begin{bmatrix} P \\ M \end{bmatrix} = \mathbf{K}^* \mathbf{u}^* = \begin{bmatrix} K_{11}^* & K_{12}^* \\ K_{21}^* & K_{22}^* \end{bmatrix} \begin{bmatrix} y_0^* \\ \theta_0^* \end{bmatrix} \quad (2)$$

where  $\mathbf{P}$  and  $\mathbf{u}^*$  are the load and displacement vectors at the pile head, respectively, in which  $y_0^*$  is the pile head displacement and  $\theta_0^*$  is the pile head rotation (anti-clockwise positive). The components of the stiffness matrix  $K_{11}^*$ ,  $K_{22}^*$  and  $K_{12}^* (= K_{21}^*)$  are the swaying, rocking and cross swaying-rocking complex stiffnesses, respectively. Due to the linear-elastic nature of the problem, the matrix is symmetric ( $K_{12}^* = K_{21}^*$ ). In addition, with the sign convention chosen, all the stiffness terms are positive at low frequency.

For convenience, it is common to separate the complex stiffness components into real-valued spring and dashpot coefficients,  $K_{ij}$  and  $C_{ij}$ :

$$\begin{aligned} K_{ij} &= \mathcal{R}[K_{ij}^*] \\ C_{ij} &= \frac{1}{\omega} \mathcal{I}[K_{ij}^*] \end{aligned} \quad (3)$$

where  $\mathcal{R}[\ ]$  and  $\mathcal{I}[\ ]$  indicate the real and imaginary components, respectively.

### 3 CLOSED FORM SOLUTION

For the homogeneous case, where  $k(z) = k$  and  $c(z) = c$ , a complex wavenumber,  $\lambda^*$  can be introduced such that equation 1 reduces to:

$$\begin{aligned} y^{*''''}(z) + 4\lambda^{*4} y^*(z) &= 0 \\ \lambda^{*4} &= (k + i\omega c - \rho_p A \omega^2) / (4E_p^* I) \end{aligned} \quad (4)$$

This expression matches the well-known governing equation for the static Winkler model, with some terms substituted for complex-valued dynamic terms. Therefore, the static solution can be employed with the corresponding substitutions. For a long pile (longer than the active length, discussed later), the head stiffness matrix is given by [4]:

$$\mathbf{K}^* = \begin{bmatrix} 4E_p^* I \lambda^{*3} & 2E_p^* I \lambda^{*2} \\ 2E_p^* I \lambda^{*2} & 2E_p^* I \lambda^* \end{bmatrix} \quad (5)$$

This expression is simple and easy to implement. However, no closed-form solutions to equation 1 are known to the authors for any inhomogeneous stiffness profiles encountered in practice. In addition, although a closed-form solution is available for piles in layered soil (in the form of successive substitution into a formula for each layer), this results in an unwieldy expression. Instead, an approximate energy solution can be employed.

#### 4 ENERGY SOLUTION

Consider a pile in equilibrium subjected to an actual deflection  $y^*(z)$  under the influence of a set of external loads at the pile head and tip; the work done by a small virtual displacement,  $y_v(z)$ , on the system can be obtained by integrating equation 1:

$$E_p^* I \int_0^L y^{*''''}(z) y_v(z) dz + \int_0^L [k^*(z) - \rho_p A \omega^2] y^*(z) y_v(z) dz = 0 \quad (6)$$

This is known as the strong form of the equation; the desired weak form can then be obtained using integration by parts and the Euler-Bernoulli beam relationships at the pile head. Note that for long piles, the base response (and therefore upper integration limit) has negligible effect on the results. Therefore, these can be expressed as improper integrals:

$$P y_v(0) + M y_v'(0) = E_p^* I \int_0^\infty y^{*''}(z) y_v''(z) dz + \int_0^\infty [k^*(z) - \rho_p A \omega^2] y^*(z) y_v(z) dz = 0 \quad (7)$$

The stiffness matrix coefficients can then be obtained by dividing equation 7 by the displacement and virtual displacement at the pile head:

$$K_{ij}^* = E_p^* I \int_0^\infty \chi_i''(z) \chi_j''(z) dz + \int_0^\infty [k^*(z) - \rho_p A_p \omega^2] \chi_i(z) \chi_j(z) dz \quad (8)$$

where  $\chi_i(z)$  and  $\chi_j(z)$  are dimensionless, unitary shape functions describing the displacement and virtual displacement variation with depth, respectively.

A similar approach has previously been employed by [5, 6, 7] to obtain pile head dashpot coefficients for the swaying mode ( $C_{11}$ ). In the form shown here (for complex pile head stiffness), the method was first employed by [8]. Analytical expressions for layered soil were first included in [4, 8], a linear Winkler stiffness profile in [9], a parabolic Winkler stiffness profiles in [10] and a power-law and an exponential Winkler stiffness profiles in [11].

These solutions have used the following shape functions from the solution for homogeneous Winkler stiffness profiles [8]:

$$\begin{aligned} \chi_1(z) &= e^{-\mu z} [\sin(\mu z) + \cos(\mu z)] \\ \chi_2(z) &= \frac{e^{-\mu z}}{\mu} \sin(\mu z) \end{aligned} \quad (9)$$

where  $\mu$  is a real-valued average wavenumber analogous to  $\lambda^*$  for the static case ( $\omega = 0$ ), the inverse of which can be used as a characteristic pile wavelength [12]. For homogeneous profiles,  $\mu$  is set equal to  $\lambda^*$  in equation 4 with  $\omega = 0$  (the static case), calculating  $\mu$  for other Winkler stiffness profiles is discussed later. Note that the component  $\mathbf{K}^*$  ( $K_{ij}^*$ ) obtained in equation 8 corresponds to the subscripts of the shape function chosen for  $\chi_i$  and  $\chi_j$  [e.g.  $K_{ij}^*$  is obtained using  $\chi_i = \chi_1$  and  $\chi_j = \chi_2$ ].

These real-valued shape functions neglect the difference in phase of the response down the pile. However, they have the significant advantage that equation 8 can easily be separated into real-valued pile head stiffness and dashpot coefficients using equation 3. The pile head stiffness terms are given by [10, 11]:

$$K_{ij} = E_p I \int_0^\infty \chi_i''(z) \chi_j''(z) dz + \int_0^\infty k(z) \chi_i(z) \chi_j(z) dz - \rho_p A_p \omega^2 \int_0^\infty \chi_i(z) \chi_j(z) dz \quad (10)$$

The first two terms (the contribution of the pile flexural stiffness and soil stiffness, respectively) make up the static pile head stiffness and are independent of  $\omega$ . The last term is the contribution of the pile inertia and is often neglected in the analysis as it is typically a minor component [11].

The pile head damping terms are given by [10, 11]:

$$C_{ij} = \frac{2\beta_p E_p I}{\omega} \int_0^\infty \chi_i''(z) \chi_j''(z) dz + \frac{2\beta_s}{\omega} \int_0^\infty k(z) \chi_i(z) \chi_j(z) dz + \int_0^\infty c_r(z) \chi_i(z) \chi_j(z) dz \quad (11)$$

where the Winkler dashpot coefficient,  $c(z)$ , is split into the (hysteretic) material and radiation components,  $c_h$  and  $c_r$ , respectively, and  $\beta_s$  is the soil hysteretic material damping coefficient. The three terms of equation 11 correspond to the contributions of the pile material damping, soil material damping and radiation damping, respectively.

The simplification in equations 10 and 11 allows the pile head response to be evaluated from a few simple, real-valued, integrals. If the inertial term in equation 10 is neglected (note that in this paper it is not), only three unique integrals need to be evaluated. The first two are common to both equations, the first of which is also independent of the Winkler stiffness profile encountered. Analytical solutions for these integrals in closed-form are collated by [11] for all of the aforementioned Winkler stiffness profiles and a simple solution is included in [13] based on the result for homogeneous profiles.

## 5 APPLYING THESE SOLUTIONS: HOMOGENEOUS SOIL

In order to apply these solutions for homogeneous soil, only the Winkler spring and dashpot coefficients must be determined.

### 5.1 Selection of $k^*$

Various solutions are available for the selection of  $k^*$ , including analytical approximations and empirical functions fitted against numerical continuum solutions. The Winkler spring stiffness,  $k$ , is often assumed to be proportional to the elastic and/or shear moduli,  $E_s$  and  $G_s$ , respectively while the radiation dashpot coefficient,  $c_r$ , is often assumed to be proportional to the soil shear wave velocity,  $V_s = \sqrt{G_s/\rho_s}$ , where  $\rho_s$  is the soil mass density. A number of available expressions are tabulated in [14, 15, 16]. In this paper, three different approaches are considered.

The first approach is the horizontal slice model employed by [1, 2, 3]. The soil is modelled as discrete, infinite, horizontal slices under zero vertical normal strain. The equivalent spring and dashpot at the pile-soil interface is then solved in rigorously in closed-form. In [3] the hysteretic material damping is incorporated using complex-valued moduli from the correspondence principle of viscoelasticity [17]:

$$\begin{aligned} G_s &\rightarrow G_s^* = G_s(1 + 2i\beta_s) \\ E_s &\rightarrow E_s^* = E_s(1 + 2i\beta_s) \\ V_s &\rightarrow V_s^* = V_s \sqrt{1 + 2i\beta_s} \end{aligned} \quad (12)$$

This results in the following expression for the complex-valued stiffness,  $k^*$ :

$$\begin{aligned} k^* &= \pi G_s^* S^2 \frac{4K_1(q)K_1(s) + sK_1(q)K_0(s) + qK_0(q)K_1(s)}{sK_1(q)K_0(s) + qK_0(q)K_1(s) + qsK_0(q)K_0(s)} \\ S &= \frac{i\omega D}{2V_s \sqrt{1 + 2i\beta_s}} \\ q &= S \sqrt{\frac{1 - 2\nu_s}{2(1 - \nu_s)}} \end{aligned} \quad (13)$$

where  $K_\nu()$  is the modified Bessel function of the second kind of order  $\nu$ . While the analytic nature of this expression is appealing, it does yield zero static stiffness at low frequencies. In addition, due to the Bessel functions, this expression cannot be conveniently separated into real and imaginary parts in closed form.

As an alternative, [18] provided the simple expression in equation 14, which was fitted against numerical finite element results for a pile embedded in a homogeneous half space. The hysteretic damping term is treated approximately by only considering the effect on the real part of the stiffness.

$$\begin{aligned} k &= 1.2E_s \\ c_r &= 5\rho_s V_s D \\ c_h &= 2\beta_s \frac{k}{\omega} \end{aligned} \quad (14)$$

Finally, the model employed by [11] is considered. This model uses the [19] approach previously applied to this problem by [20, 21], which yields an improved version of the horizontal slice model that gives finite stiffness at low frequency. However, unlike in the previous models, this is only used employed for the real-valued coefficient, for which a simplified approximate expression is developed using the asymptotic behaviour of the Bessel functions. For the radiation damping coefficient, this model employs an improved version of the cone model introduced by [7]. Each horizontal slice is split into infinitesimal independent sectors through which both shear and compression waves propagate, resulting in a frequency dependant expression in terms of Bessel functions to which [11] fit the simple expression in equation 15. The hysteretic damping term is treated using the same approximation as in equation 14.

$$\begin{aligned} k &= \frac{4\pi G_s \eta_u^2}{(1+\eta_u^2)[\ln(4/\alpha_c) - \gamma] + \ln(\eta_u)} \\ c_r &= \pi \rho_s V_s D \left[ \frac{1}{4} + \frac{4}{5} \sqrt{\frac{2}{1-\nu_s}} \right] \left( \frac{\omega D}{V_s} \right)^{-0.4} \\ c_h &= 2\beta_s \frac{k}{\omega} \end{aligned} \quad (15)$$

where  $\gamma$  ( $\approx 0.577$ ) is the Euler-Mascheroni constant,  $\eta_u = \sqrt{(2 - \nu_s)/(1 - \nu_s)}$  is a compressibility coefficient and  $\alpha_c$  is a stiffness parameter (sometimes interpreted as a dimensionless cut-off frequency). Reference [11] provides simple power-law relationships between  $\alpha_c$  and the pile-soil stiffness ratio,  $E_p/E_s$ , for different soil profiles and pile head fixity conditions. For fixed head piles in homogeneous soil  $\alpha_c$  is given by:

$$\alpha_c = 1.227 \left( \frac{E_p}{E_s} \right)^{-1/4} \quad (16)$$

## 5.2 Comparison of methods

The performance of the closed-form and energy methods for each  $k^*$  is shown in Figure 2, in comparison with numerical continuum results from [22, 23]. The former used a boundary element method developed in [24] and the latter a finite element approach. The results are normalised by the well-known dimensionless frequency,  $a_0 = \omega D/V_s$ .

In general, the analytical closed-form solution matches the continuum results reasonable well. The energy solution also performs very well at low frequencies, with a low discrepancy from the closed-form solution. However, as frequency increases, it tends to underestimate the pile head stiffness and overestimate the pile head damping coefficient.

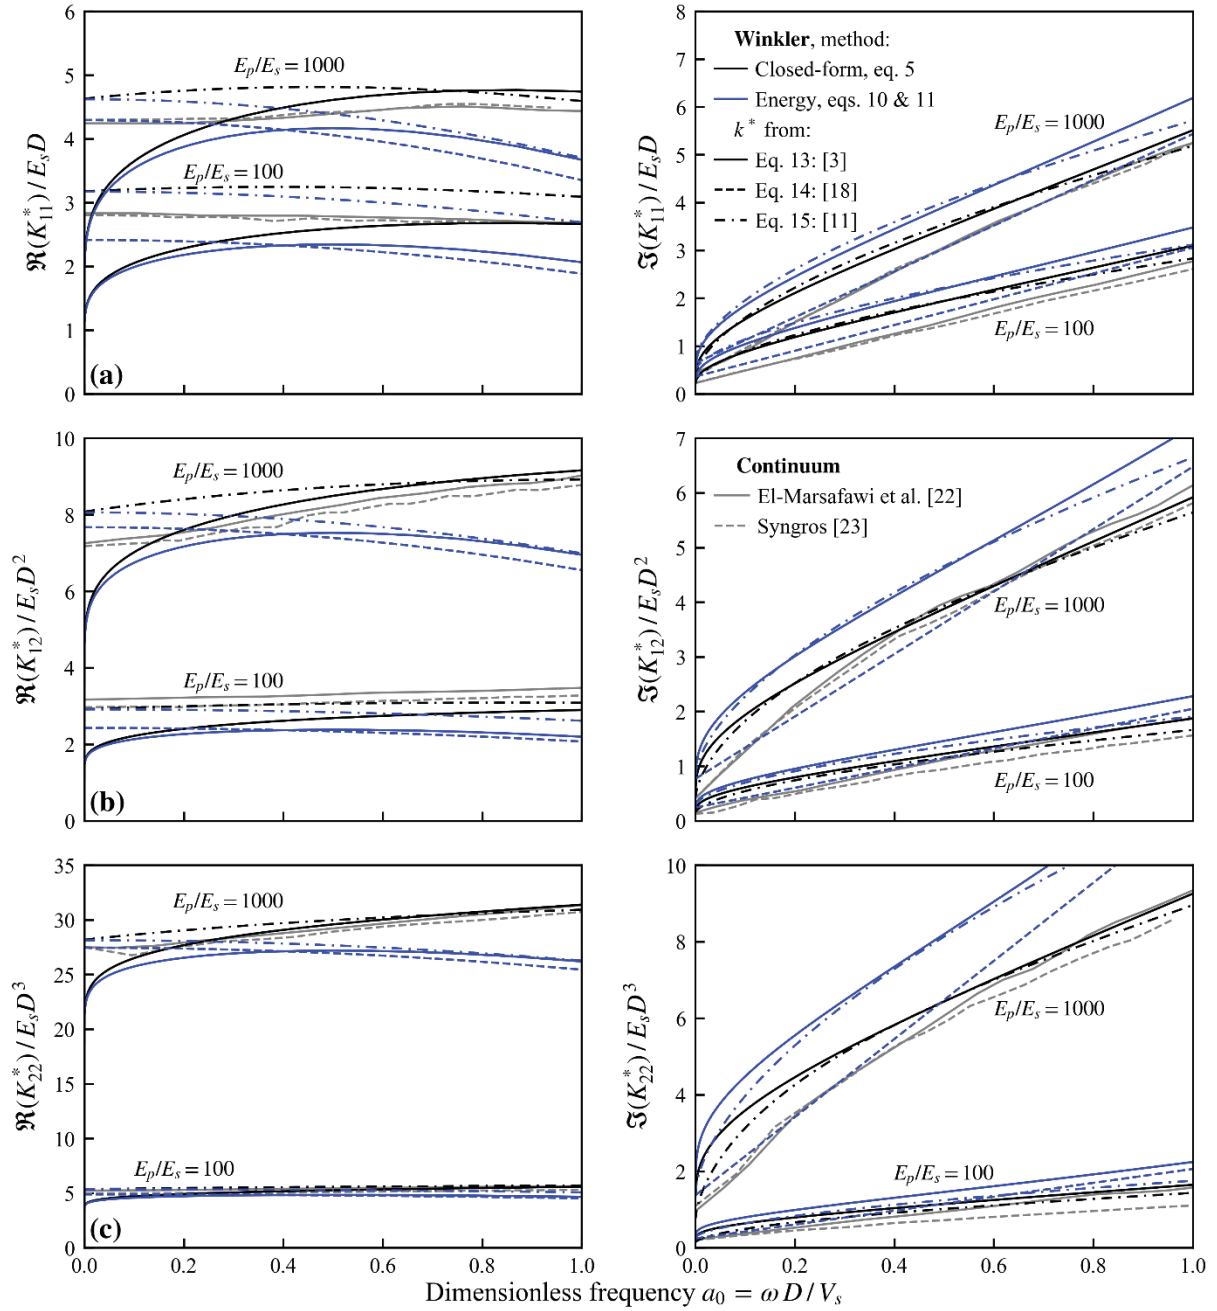

Figure 2: Normalised dynamic lateral head stiffness of piles embedded in a homogeneous half space; (a)  $K_{11}^*$  (b)  $K_{21}^*$  (c)  $K_{22}^*$  ( $\nu_s = 0.4$ ,  $\beta_s = 0.05$ ,  $\nu_p = 0.25$ ,  $\beta_p = 0.01$ ,  $\rho_p/\rho_s = 1.25$ ) (numerical data from Syngros 2004).

## 6 COMPLEX-VALUED SHAPE FUNCTIONS

In order to get better predictions at higher-frequencies, [16] suggest using complex valued shape functions,  $\chi_i^*$  and  $\chi_j^*$  based on the dynamic (rather than static) response for the homogeneous case. Therefore, equation 8 can be rewritten in the form:

$$K_{ij}^* = E_p I \int_0^\infty \chi_i^{*''}(z) \chi_j^{*''}(z) dz + \int_0^\infty [k^*(z) - \rho_p A_p \omega^2] \chi_i^*(z) \chi_j^*(z) dz \quad (17)$$

where  $\chi_1^*$  and/or  $\chi_2^*$ , given below, are substituted for  $\chi_i^*$  and  $\chi_j^*$  to get each of the complex stiffness terms as before.

$$\begin{aligned}\chi_1^*(z) &= e^{-\mu^* z} [\sin(\mu^* z) + \cos(\mu^* z)] \\ \chi_2^*(z) &= \frac{e^{-\mu^* z}}{\mu^*} \sin(\mu^* z)\end{aligned}\quad (18)$$

$\mu^*$  is now directly analogous to  $\lambda^*$ ; for homogeneous soil, if  $\mu^*$  is set equal to  $\lambda^*$ , equation 17 reproduces the complex stiffness terms from the closed-form solution exactly, as the phase difference between the responses at different depths is accounted for correctly. However, for inhomogeneous soil, the integrals in equation 17 are now also complex-valued, and harder to compute than the solution with real-valued shape functions.

## 7 APPLYING THESE SOLUTIONS: INHOMOGENEOUS SOIL

In order to compare the performance of the two different assumptions (real-valued and complex-valued shape functions), an example problem involving a pile embedded in an inhomogeneous half-space is considered. In this example, soil stiffness varies according to a linear function of depth with zero surface stiffness. As with the homogeneous case, a method to calculate  $k^*$  must be chosen. However, for inhomogeneous soil an appropriate method for selecting  $\mu$  or  $\mu^*$  must also be selected.

### 7.1 Selection of $k^*$

Only two of the  $k^*$  calculation approaches employed for homogeneous soil have been employed for this case, as the function fitted by [18] is specific to homogeneous soil. Equations 13 and 15 can be used as before, with  $G_s$  and  $V_s$  simply referring to the values at each depth, resulting in an inhomogeneous Winkler stiffness profile. In addition, the modified expression for  $\alpha_c$  for this case provided by [11] should be employed in place of equation 16:

$$\alpha_c = 1.667 \left( \frac{E_p}{E_{sD}} \right)^{-1/5} \quad (19)$$

where  $E_{sD}$  is the soil stiffness at a depth of one pile diameter.

However, the resulting functions describing the inhomogeneity in Winkler spring coefficients are not directly proportional to those describing the soil stiffness or shear wave velocity. Instead, for the solution described in equations 10 and 11, [11] suggests calculating  $k^*$  only at a depth of one diameter.  $k$  is then assumed proportional to the soil stiffness and  $c_r$  to the soil shear wave velocity (the square root of soil stiffness).

### 7.2 Selection of $\mu$

For inhomogeneous soils,  $\mu$  can be approximated as the average (static)  $\lambda$  value over a certain depth. An appropriate depth, suggested by [8], is the pile active length,  $L_a$ , which can intuitively be interpreted as the depth over which the soil stiffness has an effect on the pile head response, resulting in the following expression for  $\mu$ :

$$\mu = \frac{1}{L_a} \int_0^{L_a} \left( \frac{k(z)}{4E_p I} \right)^{1/4} dz \quad (20)$$

A number of expressions are available in the literature for  $L_a$ , based on various different definitions. Particularly useful to application is the value of  $\mu L_a = 2.5$  suggested by [25], this allows equation 20 to be used iteratively to obtain  $L_a$  and  $\mu$  for any arbitrary Winkler stiffness profile. For the specific case of power-law Winkler stiffness profiles, this was solved analytically by [26]. For the linear profile considered here this results in the expression:

$$L_a/D = \left[ \left( \frac{5}{4} \right)^8 \frac{\pi E_p}{k_D} \right]^{1/5} \quad (21)$$

where  $k_D$  is the Winkler spring stiffness at one diameter depth.

### 7.3 Selection of $\mu^*$

$\mu^*$  can be calculated using a similar approach as  $\mu$ , taking the average (complex)  $\lambda^*$  value over the active pile length:

$$\mu = \frac{1}{L_a} \int_0^{L_a} \lambda^*(z) dz$$

$$\lambda^*(z) = \left( \frac{k^*(z) - \rho_p A_p \omega^2}{4E_p^* I} \right)^{1/4} \quad (22)$$

As  $\mu^* L_a$  is complex valued, the expression suggested by [25] cannot be employed. Instead, the simple expression fitted by [23] to finite element results in the same soil profile is used here:

$$L_a/D = 2.5 \left( \frac{E_p}{E_{sD}} \right)^{1/5} \quad (23)$$

### 7.4 Comparison of methods

The performance of the two different shape function assumptions is shown in Figure 3, in comparison with numerical continuum results from [22, 23]. The results are normalised as before, using the shear wave velocity 20 diameters depth,  $V_{s,20D}$ , which was the pile length employed in the continuum solutions. An alternative normalisation,  $a_{0\mu}$ , (shown in equation 24) was suggested in [12, 27] using  $\mu$  directly. However, this was not suitable in this case due to the different  $\mu$  definition for each solution.

$$a_{0\mu} = \frac{\omega}{\mu V_s(1/\mu)} \quad (24)$$

As for the homogeneous case, the energy method with real-valued shape functions matches the continuum results for low frequencies, but significantly underestimates the pile head stiffness and overestimates the pile head damping coefficient at higher frequencies. However, the complex-valued shape functions result in a solution much closer to the continuum results. Note that a rigid boundary was employed in both continuum solutions as perfect absorbing boundaries are not available for the inhomogeneous soil profile. This is not a limitation for the Winkler model, therefore the undulations of the impedance functions and cut-off frequency evident in the continuum results are not present.

## 8 CONCLUSIONS

An energy method for predicting the head response of laterally-loaded piles according the dynamic Winkler model has been investigated and extended. The performance of the approach with the commonly employed, real-valued shape functions has been compared with numerical continuum results, as well as the closed-form (Winkler) analytical solution for homogeneous soil and an alternative solution employing complex-valued shape functions in inhomogeneous soil. Three different methods for selecting the Winkler stiffness coefficients have been employed. The following conclusions can be drawn:

- The simplifying assumption of real-valued shape functions allows analytical expressions for the (real-valued) pile head stiffness and damping terms to be obtained, such as those provided in [11].

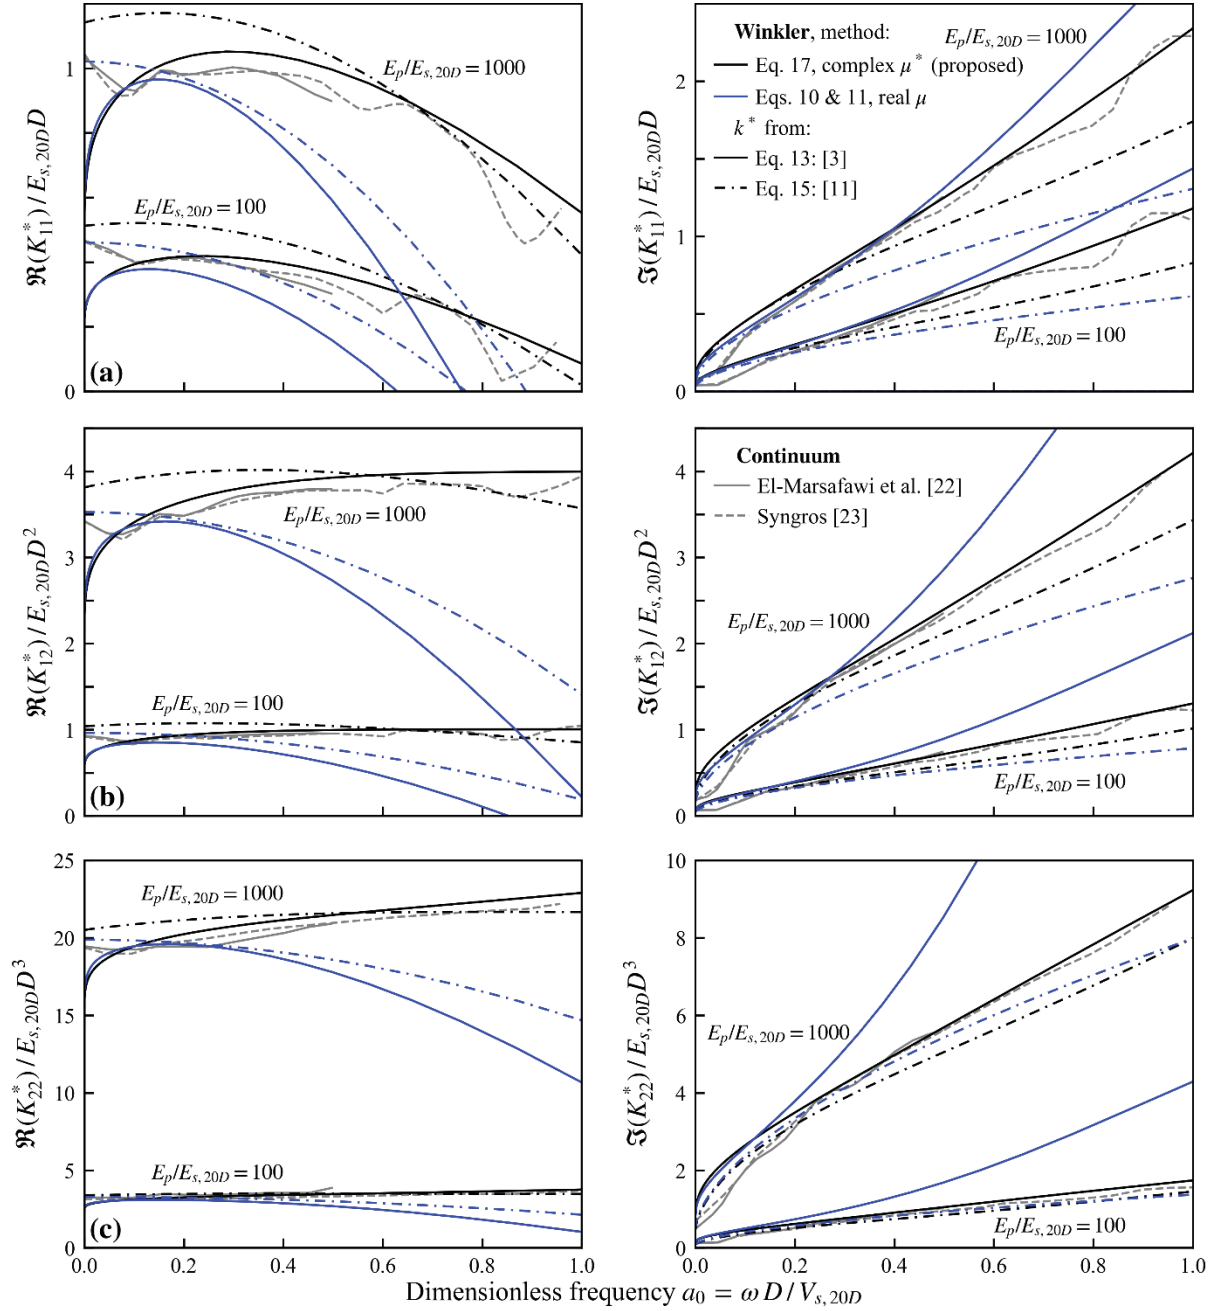

Figure 3: Normalised dynamic lateral head stiffness of piles embedded in an inhomogeneous soil with stiffness varying linearly with depth from a value of zero at the surface; (a)  $K_{11}^*$  (b)  $K_{21}^*$  (c)  $K_{22}^*$  ( $\nu_s = 0.4$ ,  $\beta_s = 0.05$ ,  $\nu_p = 0.25$ ,  $\beta_p = 0.01$ ,  $\rho_p/\rho_s = 1.25$ ) ( $L_a$  and numerical data from Syngros 2004).

- At low frequencies, the energy method with real-valued shape functions gives similar results to the analytical, closed-form Winkler solution for homogeneous soil. However, as the frequency increases it underestimates pile head stiffness and overestimates pile head damping.
- The solution employing complex-valued shape functions reproduces the homogeneous analytical solution in closed-form.
- For the inhomogeneous soil considered, both real-valued and complex-valued shape functions provide similar results at low frequencies. However, at higher frequencies the real-

valued shape functions result in underestimating pile head stiffness and overestimating pile head damping. This effect is more pronounced than for homogeneous soil.

- With the more rigorous complex-valued shape functions, the Winkler model performs well compared to the numerical continuum results in both the homogeneous and inhomogeneous soil profiles considered.

### Abstract

*In the past decades, several experimental and analytical investigations showed that the dynamic behavior of buildings can be significantly affected by the interaction with a soft foundation soil. In such cases, the actual response of structures founded on shallow foundations can be successfully simulated if the structural model is equipped with springs and dashpots calibrated through frequency-dependent impedance functions. This paper discusses the results of a research project aimed at back-calculating the impedance functions of a shallow square foundation from records of the dynamic behavior of the EuroProteas soil-foundation-structure (SFS) facility, deployed at Euroseistest (Greece). To this aim, forced-vibration tests were executed under different frequencies and increasing loading amplitudes. The experimental impedances were compared with several analytical solutions available in the literature, accounting for different hypotheses on the subsoil model. This comparison improved when the shear wave velocity  $V_s$  used to define the analytical functions was reduced accounting for the strain level mobilized by the increasing amplitude of the applied force. A numerical model was realized in the SAP2000 software. The compliance of foundation soil has been introduced using elastic springs, the stiffness of which was calibrated considering either the analytical or the experimental impedances. The fundamental frequency obtained from a modal analysis of the SAP2000 model equipped with the springs calibrated on the experimental impedances turned out to reproduce the fundamental frequency of EuroProteas effectively measured on-site. Such results showed the effectiveness of using experimental impedance functions in the numerical simulations, especially when equivalent soil parameters are hard to define.*

## 1. INTRODUCTION

It is customary in design practice to consider the structure fixed at its base, i.e. neglecting the interaction between the soil, foundation and structure (SFSI). Such hypothesis turns out to be realistic only for structures founded on very stiff soil. The up-to-date literature proves that neglecting SFSI effects may lead to an inaccurate evaluation of the actual seismic response of structures founded on soft soil [1]-[4]. The latter, instead, can be realistically simulated considering the deformability of the foundation soil through models endowed at their base through springs and dashpots [5],[6], whose stiffness and damping coefficients are calibrated through the frequency-dependent complex impedance functions.

Several analytical solutions [7]-[9] are available in the literature mostly considering simplified assumptions such as homogeneous soil with elastic behavior. Nevertheless, the equivalent stiffness in a layered soil volume involved in the foundation motion may be hard to define, if the wave velocity profile is not properly measured and accounted for. Moreover, the overburden pressure due to the structural weight can significantly influence the stress-dependent stiffness of the shallowest soil layers and, last but not the least, an increase in the loading force can lead to a non-negligible mobilization of non-linear soil behavior [1],[10]-[12].

In light of these uncertainties, full-scale experimental tests constitute an alternative strategy to evaluated frequency-dependent impedance functions. The earliest on-site studies available in the literature provided impedances for a limited range of frequency [13]-[15] or restricted to specific structures, such as an accelerograph station [16], and a nuclear reactor [17]. More recently, foundation impedance functions were identified from forced-vibration tests executed on a steel frame prototype in California [18] in the frequency range 5-15Hz.

This paper discusses the comparison between theoretical functions accounting for different hypotheses on the soil profile and the frequency-dependent experimental swaying and rocking impedances calculated from full-scale field tests on the single degree of freedom prototype EuroProteas in the EuroSeistest in Greece [19]. The objective of the study is to provide an evaluation on the reliability of field measurements of the impedance functions, in order to overcome the usual simplified assumptions on soil and foundation adopted by the analytical formulations.

## 2. IMPEDANCE FUNCTIONS

### 2.1. Definition

Impedances are complex expressions adopted to quantify the soil-foundation reaction when the structure is excited by a harmonic load,  $Fs$ , producing a shear force,  $V$ , and an overturning moment,  $M$ , on the foundation (see Figure 1a). The real part represents the stiffness and the imaginary part the radiation and material damping, which account for the energy scattered and dissipated through hysteresis in the subsoil [8]. When considering the degrees of freedom associated with the foundation swaying and rocking motion, the impedance function is a matrix that links  $V$  and  $M$  to the foundation displacement,  $u_f$ , and rotation,  $\theta_f$ . Moreover, for surface foundations, the out-of-diagonal terms can be neglected [9],[18], hence impedance matrix contains only the two diagonal terms, as follows:

$$\begin{bmatrix} \bar{V} \\ \bar{M} \end{bmatrix} = \begin{bmatrix} \bar{K}_x & 0 \\ 0 & \bar{K}_{\vartheta x} \end{bmatrix} \begin{bmatrix} u_f \\ \vartheta_f \end{bmatrix} \quad (1)$$

The terms of the impedance matrix are generally presented in the literature in the following explicit form:

$$\bar{K}_j = k_j(a_0)K_j + i\omega c_j(a_0)C_j \quad (2)$$

where  $j=x$  for the horizontal vibration and  $j=\vartheta x$  for rocking motion. The static stiffness  $K_j$ , and the dashpot coefficient,  $C_j$ , depend on the soil shear modulus,  $G$ , and Poisson's ratio,  $\nu$ , as well as on a characteristic dimension of the foundation (radius  $r$  or foundation half-width  $B$ ). The dynamic coefficients,  $k_j(a_0)$  and  $c_j(a_0)$ , depend on the vibration frequency,  $\omega$ , the characteristic dimension of the foundation,  $r$ , and the soil shear wave velocity,  $V_s$ , through the frequency factor,  $a_0 = \omega r / V_s$ .

Eqs. (1) can be solved in the frequency domain from the dynamic equilibrium of the structure-foundation system depicted in Figure 1b, as described by [19].

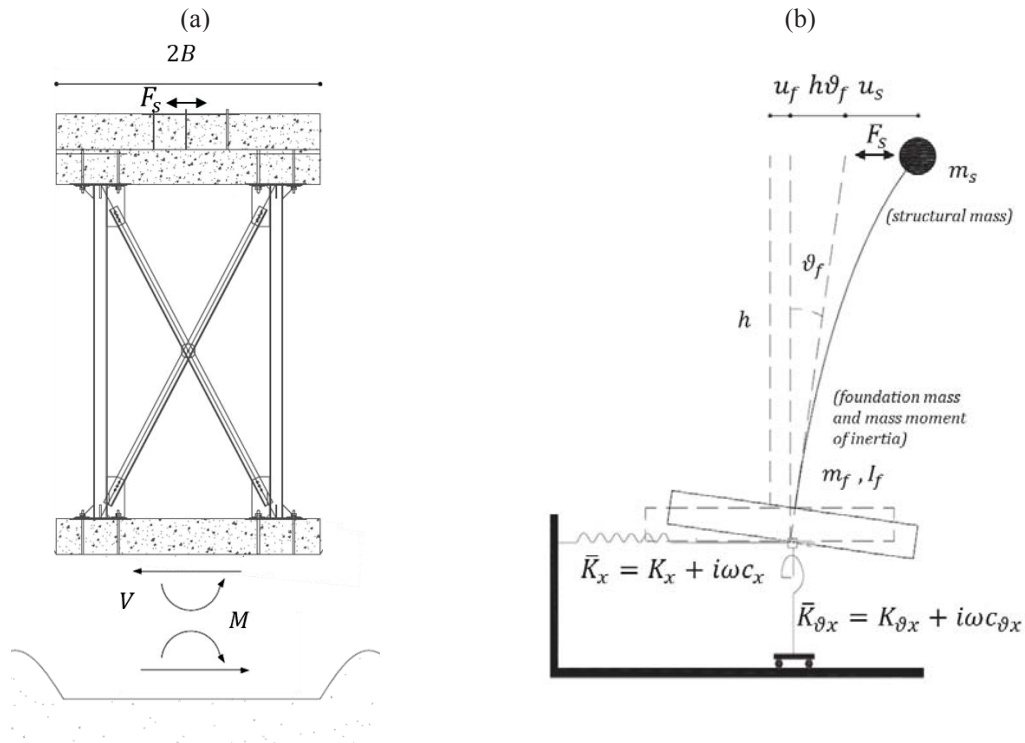

Figure 1: (a) Schematic view of the EuroProteas facility during forced vibration tests and associated reaction in the soil; (b) in-plane motion model of the single-degree-of-freedom system placed on translational and rotational springs adopted for the interpretation of experimental data. Modified after [19].

## 2.2. Analytical impedances

Different analytical functions are available in the literature for the real and complex impedance components, mostly referring to simplified conditions such as rigid massless foundation, more or less embedded in a subsoil which is typically assumed as an elastic homogeneous half-space [9],[10]. Nevertheless, [11],[20] suggest that the effect of soil inhomogeneity can be approximated with an equivalent halfspace with representative values of  $V_s$  and damping ratio averaged over depths equal to  $0.75r_{\vartheta x}$  and  $0.75r_x$ , where  $r_{\vartheta x}$  and  $r_x$  are the

rocking and swaying equivalent radii. Other widespread solutions (e.g. [21]) assume non-uniform soil profiles, including the case of a shallow layer stiffer or softer than the underlying halfspace [22]. Finally, non-linear soil behavior can play a crucial role under moderate to strong motions leading to a variation in the impedance functions. More recently, [23] introduced the effects of non-linear behavior, through a series of iterative linear analyses by updating the shear modulus and damping ratio consistently with the strain level induced by different excitation amplitudes. Reduction coefficients are then provided to reduce the real and imaginary parts of the analytical impedances by [9] when the excitation levels range from 0.01g to 1g.

Table 1 lists the analytical solutions and the associated hypotheses on the subsoil model adopted in this study to characterize the analytical impedance functions used for comparison with the experimental impedances back-calculated by [19]. The classic solution by Pais and Kausel [9] for a homogenous elastic halfspace was firstly selected for comparison; these equations are very similar to the widespread expressions given by [8] which therefore were not considered. Then, among all the different combinations of shear moduli of the layer and halfspace by Liou [22], a 50% reduction was considered between the shear moduli of the halfspace medium and that of the foundation deposit layer (i.e.  $G_2/G_1=0.5$ ). Finally, the solution by [23], accounting for soil nonlinearity, was checked. The dynamic coefficients corresponding to 0.01g and 0.2g were multiplied for the static stiffness expressions provided by [9].

### 3. EXPERIMENTAL TESTS ON THE SISIFO PROJECT

#### 3.1. Experimental facility: EuroProteas in the Euroseistest

The above theoretical impedance functions were compared with the experimental results of the research project "Seismic Impedance for Soil-structure Interaction From On-site tests, SISIFO", funded by the HORIZON2020-supported program SERA the Seismology and Earthquake Engineering Research Infrastructure Alliance for Europe (<http://www.sera-eu.org/en/home/>). The SISIFO project aimed to investigate the effectiveness of different procedures of experimental identification of the impedance functions at prototype scale. For this reason, on-site tests were performed on the full-scale experimental facility of EuroProteas (Figure 2a) in the Euroseistest TST site located in the middle of Mygdonian valley in Northern Greece (Figure 2b).

EuroProteas consists of a simple steel frame supported by a 3m x 3m x 0.4m foundation raft, overtopped by two interconnected slabs each one of them identical to it (Figure 2a). The steel frame consists of four squared hollow steel columns (QHS 150mm x 150mm x 10mm) clamped on the foundation through steel bolts. L-shaped cross-braces (100mm x 100mm x 10mm) rigidly connect the steel columns all around the structure. The raft can be considered as an ideal 'shallow foundation' since the surrounding soil was intentionally removed before the execution of the tests discussed in the following. More details on the structural features are discussed by [19] and [24].

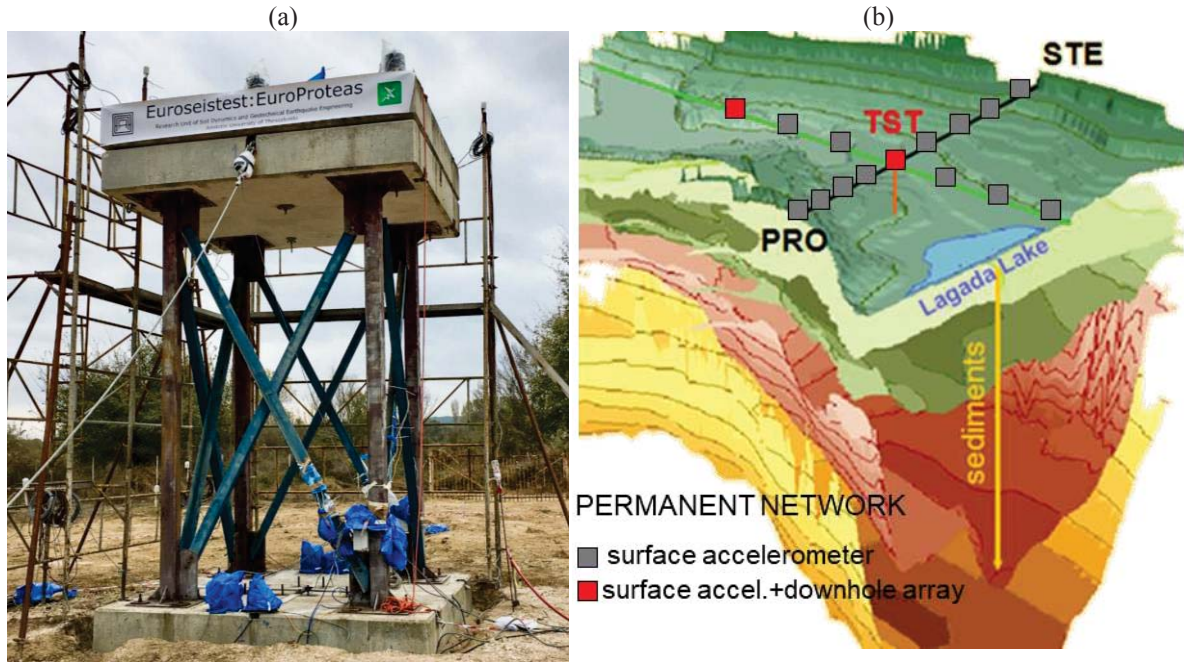

Figure 2 (a) Full-scale experimental facility of EuroProteas located (b) in the TST site, in the middle of the EuroSeistest.

The foundation subsoil was investigated and its dynamic properties were defined on the basis of extended geophysical and geotechnical in-situ and laboratory surveys reported in earlier studies [24]-[27]. The soil profile is composed of a first layer of silty-clayey sand about 7m thick, a layer of clayey-silty sand with local contents of gravel between 7m and 22m, and the last layer of marly silt and silty sand down to a depth of 30m. The shear wave velocity of the uppermost 6m was found to vary between 150m/s, as resulting from a DH test, and 100m/s, from the interpretation of further geophysical tests (see Figure 3a).

All the  $V_S$  profiles shown in Figure 3a refer to free-field investigations performed before the construction of the prototype. However, it must be observed that the increment of the mean effective stress due to the structural weight may have caused an increase in the initial shear stiffness at the shallowest depths [28]. Therefore, as suggested by [11],[18], the free-field velocity ought to be corrected to account for such a stiffening, by multiplying  $V_S$  for an overburden correction factor (hereafter  $OCF$ ) which can be computed as follows:

$$OCF = \left( \frac{\sigma'_v(z) + \Delta\sigma'_v(z)}{\sigma'_v(z)} \right)^{n/2} \quad (3)$$

where  $\sigma'_v(z)$  and  $\Delta\sigma'_v(z)$  are the effective vertical lithostatic stress and its increment due to the structural weight,  $n$  is an exponent increasing with soil plasticity index [29],[30]. Figure 3b reports the variation of  $OCF$  with depth between  $z=0.1$ m and  $z=6$ m (black solid line), calculated assuming  $n=0.5$  and adopting the Steinbrenner's solution for the vertical stress increment [31]. As expected,  $OCF$  is maximum at the foundation level and sharply decreases with depth. Previous studies in the literature [20] suggest to correct  $V_S$  profiles for  $OCF$  values averaged through appropriate depth intervals, in order to obtain a mean equivalent velocity profile. Following such a suggestion, Figure 3b also reports the values of  $OCF$  averaged over 50% (red solid line) and 100% (blue solid line) of the foundation width, i.e.  $2B$ .

The average increase of the free-field  $V_S$  is estimated to be equal to 35% ( $\overline{OCF}_B=1.35$ ) up to the foundation half-width,  $B$ , and 22% ( $\overline{OCF}_{2B}=1.22$ ) up to the total foundation dimension,  $2B$ . It follows that the actual velocity profile may present an inversion, with a greater value of  $V_S$  in the shallowest range of depths (i.e., that most interested by the foundation rocking motion) with respect to the soil volume mobilized by the foundation swaying.

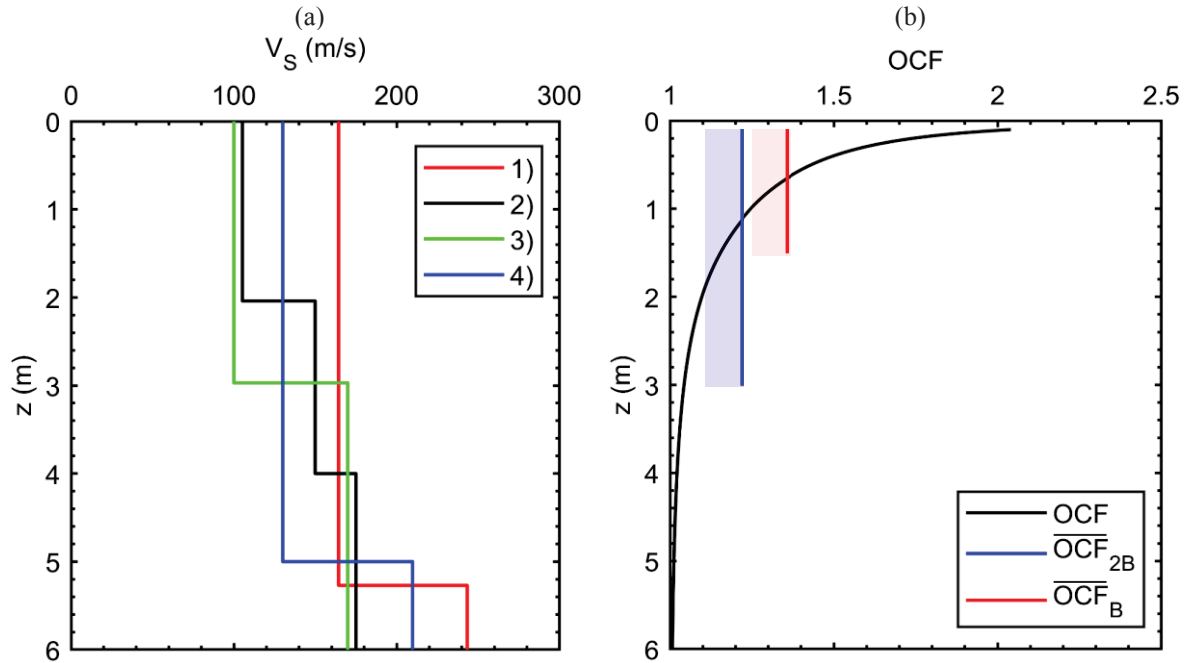

Figure 3 (a) Shear wave velocity profiles from 1) down-hole test before EuroProteas construction, 2) at a site approximately 50m away from the facility [25], 3) reference model of the valley cross-section from updated geophysical, geotechnical and numerical modeling [26], 4) profile from detailed geotechnical and geophysical surveys [27], as adapted from [24]; (b) overburden correction factor,  $OCF$ , for the EuroProteas foundation soil and its average along the foundation half-width,  $B$ , and width,  $2B$ .

### 3.2. Instrumentation layout and performed tests

The facility was instrumented with triaxial accelerometers (CMG-5TD and CMG-5TCDE, Guralp Systems Ltd) to record both the structural and the foundation response (Figure 4). In particular, the instrumentation layout consists of 5 accelerometers mounted on the roof, three along the axis parallel to the direction of shaking (in-plane) and two at the opposite corners of the slab, to capture possible out-of-plane motion. Additionally, four triaxial accelerometers were mounted in pairs at the opposite edges of the foundation slab along the direction of shaking, in order to ensure and validate the proper recording of the foundation's translational and rotational response. All the instruments were connected to external global positioning system (GPS) antennas and their sampling frequency was set to 200Hz. They were oriented along the positive  $x$ -direction of loading, which forms an angle of 30 degrees with the magnetic North. However, for sake of simplicity, the  $x$  and the  $y$  component of each record were tagged as North and East, respectively, as shown in Figure 4.

The dynamic response of the instrumented facility was firstly identified under random ambient noise test, in which the structural response was recorded with no external excitation. Free-vibration tests were also carried out by a ‘snap-back’ procedure, in which the roof was initially slightly displaced and thereafter released to induce the free vibration of the prototype structure (see [19]). The structure was then subjected to sinusoidal forced vibration tests, by

changing the frequency in a range of interest of earthquake engineering, i.e. from 1Hz to 10Hz, through a shaker mounted on the roof slab. The MK-500U (ANCO Engineers Inc) eccentric mass vibrator system was adopted as a source of harmonic excitation. The following equation controls the generated harmonic load:

$$F_s = E(2\pi f)^2 \sin(2\pi ft) \quad (4)$$

The frequency of the shaker force was held constant until the system reached the steady state. Four different forced vibration test series were executed, by changing the frequency of the excitation and adjusting the rotating mass through the vibrator's eccentricity of the shaker. Each applied frequency was locked for 60s and then incremented by 1Hz steps in the range 1Hz – 10Hz. The frequency step was reduced to 0.5Hz when approaching the first vibration mode, in order to more accurately record the resonance response.

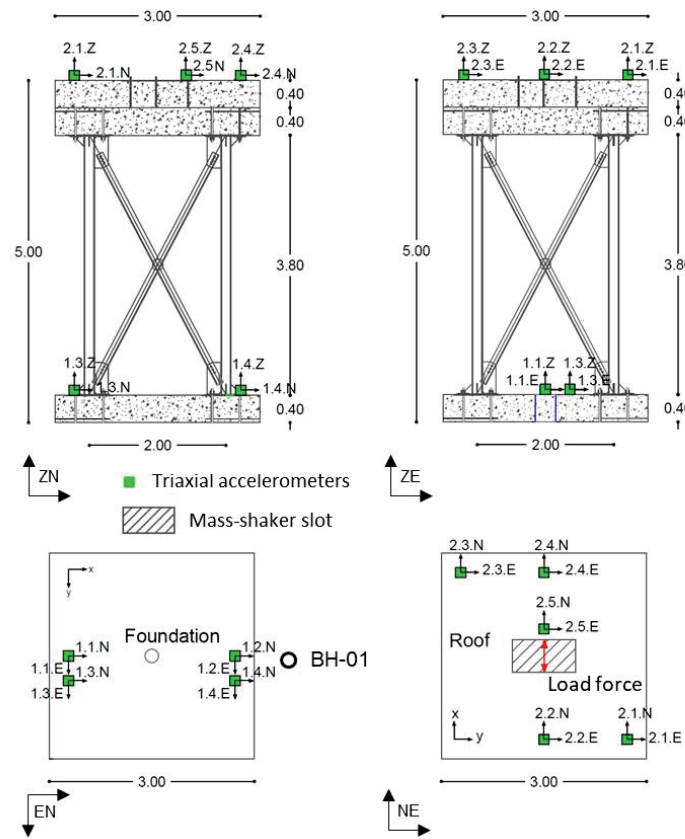

Figure 4 Instrumentation layout of the facility during the forced vibration tests.

Table 2 reports the details of the lowest and highest force amplitude tests, i.e. Forced-A and Forced-D, yielding the experimental impedance functions which were taken for comparison with the analytical solutions listed in Table 1.

Experiment	Frequency range $f = \omega/2\pi$	Force range (min-max) $E\omega^2$
(-)	(Hz)	(kN)
Forced-A	1-2-3-3.5-4-4.5-5-6-7-8-9-10	0.07-7.30
Forced-D	1-2-2.5-3-3.5-4-5-6-7-8	0.45-28.58

Table 2 Force and frequency range applied during Forced-A and Forced-D tests.

### 3.3. Experimental impedance functions

As detailed in [19], experimental impedance functions were back-calculated through Eqs. (1) from the data recorded during the forced vibration tests. The left side of the system of Eqs. (1) are the shear force,  $V$ , and the overturning moment,  $M$ , acting on the foundation. In the time domain, they result from the difference between the applied loads ( $F_s$  and  $F_s h$ ) and the inertia forces generated by the structural mass,  $m_s$ , the foundation mass,  $m_f$ , and its mass moment of inertia,  $I_f$ . The computational details are reported in [19] and here omitted for sake of brevity. The right side of Eqs. (1), i.e. the displacement array, defines the motion of the rigid foundation slab by two independent swaying,  $u_f$ , and rocking,  $\vartheta_f$ , kinematic components.

The foundation rocking,  $\vartheta_f$ , was computed as the difference between the double integration of vertical records 1.3Z and 1.4Z, divided by their distance. The foundation swaying,  $u_f$ , was calculated from the displacement obtained by integrating the acceleration recorded by sensor 1.4N minus the displacement induced by the foundation rocking, i.e.  $\vartheta_f h_f$ . The applied force defining the load vector was calculated according to Eq. (4), where the phase angle,  $\varphi$ , between the applied force itself and the response was assumed to equal to that characterizing the force-displacement time shift of a simple SDOF oscillator [32] with the overall damping  $\xi=5\%$  and the natural frequency  $f_n = 3.4\text{Hz}$  for Forced-A and  $3.0\text{Hz}$  for Forced-D which were inferred from the interpretation of noise and snap-back tests [19].

Figure 5 shows the real part of impedance functions calculated in [19] from Forced-A (full circles) and Forced-D (hollow circles) tests, for both swaying and rocking motions. As it can be observed from the plots, both swaying and rocking dynamic stiffness decrease with the increment of the excitation force, i.e. from Forced-A to -D, apparently due to the mobilization of non-linear soil behavior.

Figure 5 Comparison between the real part of impedance functions back-calculated from Forced-A (full circles) and Forced-D (hollow circles) vibration tests for swaying and rocking motion

### 3.4. Evidence of non-linear soil behavior from the experimental data

Mobilization of nonlinearity in the soil leads to a decrease of soil stiffness and to an increase of hysteretic damping, consequently modifying the foundation motion. For such a reason, soil properties defining impedance functions must be selected to properly account for the mobilized shear strain levels. An estimate of the peak shear strain amplitude,  $\gamma_{eff\max}$ , can be obtained from the ratio between the peak horizontal velocity recorded on the foundation,  $\dot{u}_f$ , and the shear wave velocity,  $V_s$  [33],[34].

The resulting mobilized shear strains during the Forced-A and -D tests are reported in Figure 6a. As expected, the strain amplitude increases with the level of the applied force, i.e. from Forced-A to -D. The system reaches the highest peak shear strain close to the resonance of the facility, i.e. around 3.0 and 2.5Hz, respectively under the Forced-A and -D tests [19],[35]. In correspondence of these values,  $\dot{u}_f$  resulted equal to 0.25cm/s and 0.9cm/s, which combined to a  $V_s$  equal to 100 m/s (see Figure 3a), yields to  $\gamma_{eff\ max}$  of the order of 0.0025% for Forced-A (blue hexagon in Figure 6a) and 0.009% for Forced-D (red hexagon in Figure 6) respectively. Figure 6b shows the variation of normalized shear modulus with the shear strain resulting from a resonant column test (reported in [24]) on a sample taken at a depth between 2.7m and 3.0m, from the borehole BH-01 close to the foundation. The plot revealed that the peak shear strain  $\gamma_{eff\ max}$  estimated for the Forced-A test is associated with a negligible reduction of the shear modulus, while  $\gamma_{eff\ max}$  for the Forced-D test produces a reduction of the shear modulus of the order of 25% of its initial value. Hence, soil nonlinearity is expected to affect rather significantly the experimental impedances derived from the Forced-D test.

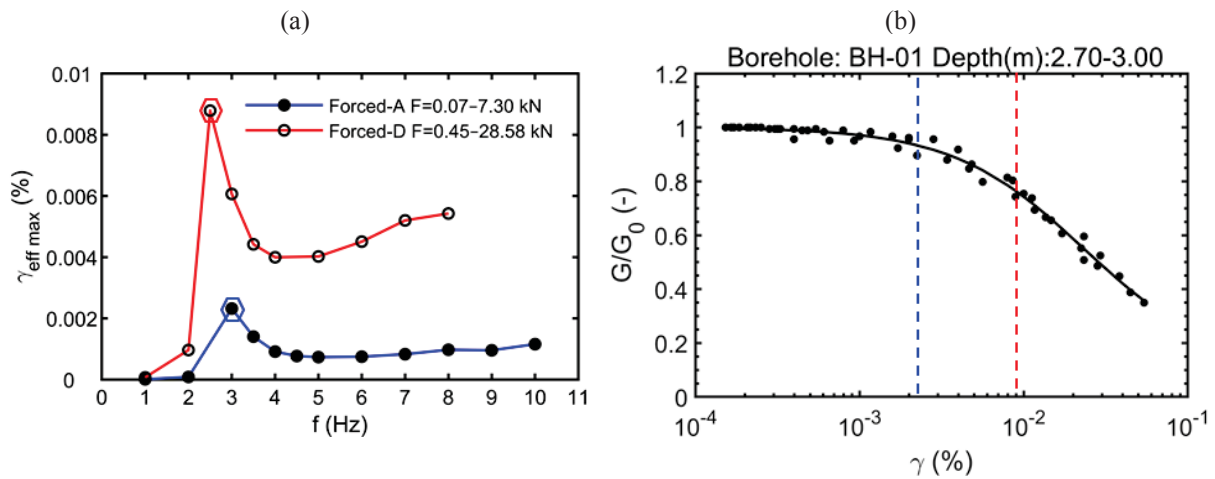

Figure 6 (a) Effective peak shear strain mobilized during Forced-A (full circles connected with a blue solid line) and Forced-D (hollow circles connected with a red solid line) tests, with resonance peaks highlighted by a blue and red marker, respectively; (b) peak strain amplitudes drawn with the same colors across the shear modulus reduction curve  $G/G_0$  (as adapted from [24]).

#### 4. CALIBRATION OF ANALYTICAL SOLUTIONS AGAINST ON-SITE IMPEDANCE FUNCTIONS

The best-fitting between the analytical and experimental impedances was investigated by changing the  $V_s$  value in the computation of the analytical value until the difference with the experimental impedance was minimized. Being both the impedances variable with frequency (see for instance Figure 5) the  $V_s$  was computed by minimizing the sum of the squares of the residuals (or offsets), defined as the difference between the analytical ( $K_{anal}$ ) and experimental ( $K_{exp}$ ) real part of impedances as follows:

$$RSS = \sum_{i=1}^n \left( K_{exp\ i} - K_{anal\ i}(V_s) \right)^2 \quad (5)$$

where  $i$  indexes the frequencies listed in Table 2.

The resulting  $RSS$  normalized with respect to the maximum value, i.e. that associated with  $K_{\theta x}$  under the test Forced-A, are reported in Table 3 along with the best-fitting  $V_s$  values.

	Forced-A					Forced-D			
	swaying		rocking			swaying		rocking	
	$(K_x)$		$(K_{\theta x})$			$(K_x)$		$(K_{\theta x})$	
	$V_S$	$RSS$	$V_S$	$RSS$		$V_S$	$RSS$	$V_S$	$RSS$
	m/s	%	m/s	%		m/s	%	m/s	%
Pais and Kausel	89	6	99	100	Pais and Kausel	77	5	81	34
Liou ( $G_2/G_I=0.5$ )	96	3	98	57	Liou ( $G_2/G_I=0.5$ )	83	2	79	20
Pitilakis et al. (0.01g)	92	6	96	68	Pitilakis et al. (0.2g)	95	3	96	34

Table 3 Minimum dimensionless values of Residual Sum of Squares ( $RSS$ ) associated with the shear wave velocity ( $V_s$ ) used to define the best-fitting analytical function for the swaying and rocking dynamic stiffness back-calculated after Forced-A and Forced-D tests.

The best-fit analytical stiffness is compared in Figure 7a for the swaying and in Figure 7b for the rocking motion to the experimental data of Forced-A (left) and Forced-D (right) tests.

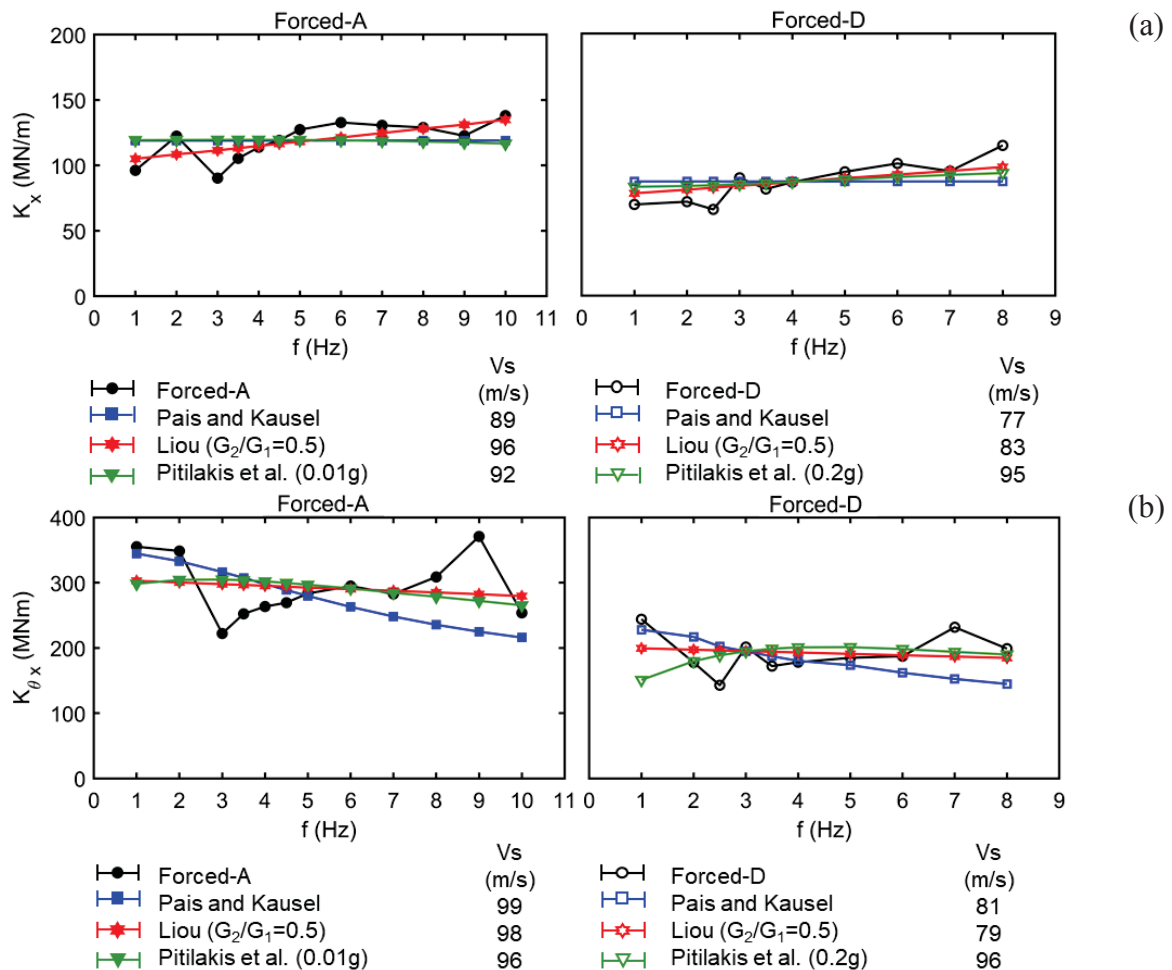

Figure 7 Comparison between the real part of experimental and analytical functions accounting for different values of shear wave profile for the foundation (a) swaying and (b) rocking for (left) Forced-A and (right) Forced-D tests.

For a given analytical solution, the best-fitting  $V_S$  depends on the considered foundation motion. With reference to the results of the Forced-A test, the highest discrepancy is observed for the solution by Pais and Kausel [9], which requires a  $V_S=89$  m/s to match the experimentally derived swaying impedance and a  $V_S=99$  m/s (i.e. with an increase of 11% with respect to the swaying) to match the rocking component. As it is well known [20],[36], the soil depth involved by foundation rocking is almost equal to the foundation half-width and that associated with the swaying motion to the foundation width. Hence the stiffness increase due to the EuroProteas overburden is expected to affect the rocking more than the swaying motion. As shown in Section 3.1 and Figure 3b, the relative difference between the OCF averaged up to the foundation halfwidth and width,  $\overline{OCF}_B$  and  $\overline{OCF}_{2B}$ , is exactly equal to 11%, i.e. that between the  $V_S$  values required to fit the rocking and swaying motions.

From a visual analysis of Figure 7 it appears that the best overall agreement between analytical solutions and experimental data (black symbols) is reached when considering the heterogeneous subsoil profile proposed by Liou [22] (red symbols). As reported in Table 3, such analytical impedances are associated with the lowest RSS for both swaying and rocking modes. Conversely, when considering analytical functions under simplified assumptions such as homogenous soil model (i.e. Pais and Kausel [9]), the match with experimental functions worsens (blue symbols) and the greatest RSS values are reached.

Both Table 3 and Figure 7 show that the "best fitting" shear wave velocity reduces when considering the Forced-D tests. Table 4 lists the ratio between the  $V_S$  used to define the analytical expressions for the best-fitting of Forced-D test results and the corresponding value for the Forced-A, for the two considered foundation motions.

	$V_{S \text{ Forced-D}}/V_{S \text{ Forced-A}}$	
	swaying	rocking
Pais and Kausel[9]	0.86	0.82
Liou ( $G_2/G_1=0.5$ )[22]	0.86	0.81
Pitilakis et al. [23]	1.03	1.00

Table 4 Shear wave velocity reduction from Forced-A to Forced-D, for both swaying and rocking motions.

The normalized shear wave velocity reduction ranges between 14% and 19% when adopting Pais and Kausel [9] and Liou [22] solutions. Such values are coherent with the experimental data reported in Figure 6b, revealing a reduction of the normalized shear modulus up to 25%, hence a  $V_S$  reduction up to 13%. When soil nonlinearity is directly considered in the analytical solution, as suggested by Pitilakis et al. [23], the best-fitting  $V_S$  is the same for the Forced-A and Forced-D tests, since soil properties consistent with the level of shear strain induced by shaking (i.e. 0.01g and 0.2g) are considered by the approach itself.

Finally, it is worth highlighting that the value of  $V_S$  matching the Forced-D test is less affected by the foundation motion than those matching the Forced-A. This is due to the fact that rocking motion mobilizes higher strain levels concentrated in the very shallow foundation soil, reducing its stiffness. Hence the initial inversion induced by the structural weight (see Section 3.1) is reduced, making the stiffness in the soil volume affected by the rocking and swaying motions more homogeneous.

## 5. NUMERICAL SIMULATION

A numerical simulation (Figure 8) with the finite element software SAP2000 allowed to determine the fixed-base (FB) and compliant-base (CB) dynamic response of the prototype.

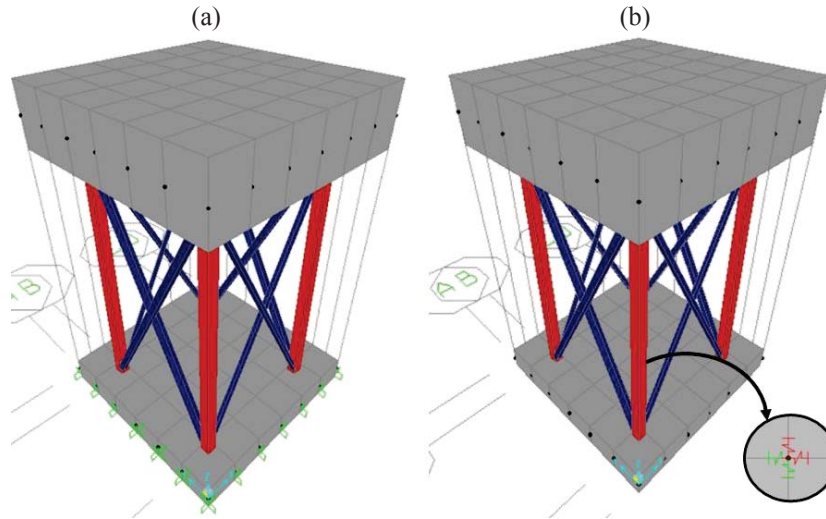

Figure 8 Numerical model for (a) the fixed-base, FB, and (b) compliant-base, CB, prototype.

Following the substructure approach, the numerical simulation of the compliant-base model, CB, was performed by restraining the base of the structural model with a system of springs. Their translational and rotational stiffness values were firstly characterized from the real part of the ‘linear’ experimental impedances, as resulting from Forced-A test for both swaying and rocking modes, with reference to the fundamental frequency of the system, i.e. 3Hz (see [19]), as in the usual procedure. To highlight the effectiveness of using experimental functions, the analysis was repeated by considering each analytical function listed in Table 1. In such a case, the calibration procedure followed in Section 4 was ignored and the shear wave velocity was assumed from the free-field measurements in Figure 4, as commonly done in lack of experimental impedance values. The minimum value of the range 100m/s - 150m/s of  $V_s$  measured in the uppermost 3 m of the layered soil profile was assumed, i.e. 100 m/s (Figure 3).

Results of modal analyses performed on the fixed-base and compliant-base models are reported in Table 5. They confirmed the expected strong influence of the soil-structure interaction on the dynamic response of the facility. In all cases, the fundamental frequency is significantly lower than the value of 9.13Hz resulting from the fixed-base model. Only when characterizing the springs with the experimental impedances, the results of the modal analysis were consistent with the on-site measurements, identifying a fundamental frequency around 3.0Hz under the Forced-A test. Such evidence highlights that the calibration of the compliant-base model through experimental impedances is possible and is even more accurate than the traditional analytical impedance functions because it implicitly accounts for soil inhomogeneity and nonlinearity, which are either neglected or hard to be quantified in the definition of analytical formula.

Foundation restraining system	frequency (Hz)	period (s)
FB (Fixed-base)	9.13	0.11
CB (Forced-A)	3.05	0.33
CB (Pais and Kausel [9])	3.11	0.32
CB (Liou ( $G_2/G_1=0.5$ ) [22])	3.38	0.30
CB (Pitilakis et al. (0.01g) [23])	3.44	0.29

Table 5 Fundamental frequency and period associated with the dominant response of the structure for the fixed-base and compliant-base conditions, considering experimental and analytical impedance functions.

## 6. CONCLUSIONS

The response of a structure resting on soft soil conditions may be different compared to the fixed-base assumption. In the up-to-date literature, SFSI is incorporated in the analysis of shallow foundations using the uncoupled 'substructure method'. The foundation compliance is taken into account through frequency-dependent impedance functions.

Several analytical functions are available in the literature depending on soil and foundation properties, varying with depth and strain level. In this study, theoretical functions accounting for different hypotheses on the subsoil model were calibrated against the impedance functions of a shallow square foundation back-figured from records of the dynamic behavior of the EuroProteas soil-foundation-structure (SFSI) facility, in the framework of the SISIFO project.

The experimental impedances evaluated under different values of forces applied by the shaker match reasonably well with the analytical frequency-dependent impedance functions calculated for varying shaking levels when changing the foundation soil properties according to the mobilized shear strain.

In this study, the agreement was found to increase considerably when considering an inversion in the soil velocity profile, as for the theoretical impedances proposed by Liou [22]. Such an effect is probably due to the increase of shear stiffness induced by the overburden pressure. To overcome the above limitation, future experimental campaigns addressed to evaluate impedance functions should include shear wave measurements after the installation of the prototype, for instance by means of a hole across the foundation slab, allowing for the execution of down-hole or cross-hole tests.

Moreover, when increasing the frequency-dependent amplitude of the force applied through the shaker, significant non-linear effects are induced; for such a reason, laboratory tests on specimens representative of the soil beneath the foundation are needed to investigate the role of inelastic soil behavior even at the lowest strain levels.

A numerical simulation in the SAP2000 software confirmed the effectiveness of using experimental impedance functions, especially when the soil parameters are hard to be defined. The comparison among the obtained predominant frequencies of the model equipped with springs calibrated on the experimental and analytical functions highlighted that the fundamental frequency of EuroProteas measured on-site is well-reproduced only if the experimental impedances are adopted in the analysis.

In conclusion, measurement of the foundation impedance can be a sound alternative strategy with respect to the predictive formulae. It does not require over-simplified assumptions on the geometrical and mechanical properties of both foundation and subsoil.

## 7. ACKNOWLEDGMENT

The Authors acknowledge support by the project "Seismology and Earthquake Engineering Research Infrastructure Alliance for Europe (SERA)". This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 730900. The first Author has received fundings from the European Union's H2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement N° 813137, project URBASIS. OASP-ITSACK is also acknowledged for providing part of the instrumentation and manpower for the execution of the tests.

### Abstract

Soria arch dam and reservoir is the largest infrastructure of this type that exists in the Canary Islands both in capacity and height which is located in the Island of Gran Canaria. The goal of this paper is the development of a numerical model for the analysis of the dynamic and seismic behavior of this arch dam. To do so the effects of the ground motion and of the canyon geometry on the dynamic response of the arch dam are studied in this paper. The seismic response of the arch dam subject to time harmonic shear waves impinging the dam site with a horizontal upstream and cross-stream free-field ground surface motion is analyzed. The numerical model includes both the concrete arch dam and the surrounding area, so that soil-structure interaction phenomena can be taken into account as accurately as possible. The model is used to evaluate the magnitude of soil-structure interaction and also the influence of the accuracy of the geometrical representation of the surrounding topography on such soil-structure interaction effects. To this end, two different numerical models are built. On the one hand, a Finite Element Model of the actual geometry of the concrete dam wall is developed and used to perform a modal analysis of the fixed-base model. On the other hand, several three-dimensional frequency-domain Boundary Element models of both the concrete dam and the surrounding topography are built; all of these models include the actual geometry of the dam wall and different approximations of the surrounding soil, ranging from a very simplified straight prismatic canyon to an elaborate model of the actual topography. These BEM models are used not only to estimate compliant-base natural frequencies and mode shapes, but also to study the seismic response of the system when subjected to incident planar seismic waves. The results show that the influence of the soil—structure interaction effects on the dynamic response of the system is quite significant. It is also shown that the asymmetry of the canyon might significantly affect the seismic response of the dam wall.

**Keywords:** Arch dam, Boundary Element Method, dynamic soil—structure interaction.

---

## 1 INTRODUCTION

Located in the south of the Island of Gran Canaria, between the municipalities of Mogán and San Bartolomé de Tirajana, the Soria dam is a concrete double-curvature arch dam. Soria arch dam and reservoir is the largest infrastructure of this type that exists in the Canary Islands both in capacity ( $32 \text{ hm}^3$ ) and height (120 m). The structure was constructed from 1962 to 1972. It is 120 meters in height (above foundation) and with a thickness of the crown cantilever decreasing from 17.30 m at the base to 3 m at the crest. It is provided with 5 galleries inside its body [1]. Some pictures of Soria dam are shown in Figure 1.

**Figure 1** : Soria arch dam (Gran Canaria).

The present study aims at building a three-dimensional numerical model for the analysis of the dynamic and seismic behavior of the Soria arch dam in order to analyze the influence of the soil-structure interaction effects, and of the accuracy of the geometrical representation of the surrounding topography.

## 2 METHODOLOGY

Firstly, a geometrical model was developed consisting of two parts: the dam wall and the canyon. The geometry of the dam wall was constructed according to the information gathered from a specific study made in 1991 [2]; on the other hand, a geometrical representation of the actual canyon and surroundings was obtained from topographic information available in the databases of Gobierno de Canarias [3].

Secondly, a modal analysis was carried out. For that, a 3D finite element model of the dam wall was developed to obtain the mode shapes of vibration of the fixed-base model. Displacements along the abutments and base of the dam wall are assumed to be zero in this case (Figure 2). The finite element mesh corresponding to the geometry of the dam wall was constructed by means of 4250 tetrahedral 3D elements and 7805 nodes (Figure 3). For the Finite Element Analysis, Code\_Aster was used, which is a Finite Element Analysis software engine [4].

**Figure 2**: Boundary conditions in modal analysis.

**Figure 3:** 3D mesh used for the FEM analysis. (a) downstream side view, (b) upstream side view and (c) top view.

Thirdly, to illustrate the differences in the dynamic response of the soil-structure system, harmonic analyses of the system, considering both fixed- and compliant-base configurations, were carried out using the multidomain Boundary Element Method (BEM) code in the frequency domain described in Maeso et al. [5, 6]. Wall and surrounding ground are modelled by means of boundary integral equations discretized into boundary elements, taking into account their specific characteristics and the interaction between them by using existing compatibility and equilibrium relationships on the variables defined for structure and soil in the nodes of the contact surfaces. Nine node quadratic quadrilateral elements and six node quadratic triangular elements with a parabolic approximation are used for the boundary elements discretization. The size of the wall elements is determined by the wavelength in the dam wall while in the soil free surface it is gradually increased as the distance from the area of interest increased. The Boundary Element Method allows to take intrinsically into account the unbounded character of the soil medium, without the need of absorbing boundaries or any other mathematical artifact. On the contrary, the free-field mesh is truncated at a distance such that only the scattered wave fields are sufficiently damped. Both structure and soil are considered as solid viscoelastic materials applying in these regions Navier's equation.

Figure 4 shows the boundary element mesh used for the fixed-base model. The influence of soil-structure interaction and of the accuracy of the geometrical representation of the surrounding topography on such soil-structure interaction effects needs to be evaluated. In order to do so, three of the BE discretizations are used. Figures 5, 6 and 7 show the actual geometry of the dam wall with different approximations of the surrounding soil, from a straight prismatic canyon with two different amounts of free-surface (Figures 5 and 6, free-surface extensions equal to two and three times the height of the dam wall, respectively) to a model of the actual topography (Figure 7, free-surface extensions equal to two times the height of the dam wall). As mentioned before, these four BEM models have been constructed by means of nine-node quadratic quadrilateral elements and six-node quadratic triangular elements where the number of nodes and elements are shown in table 1.

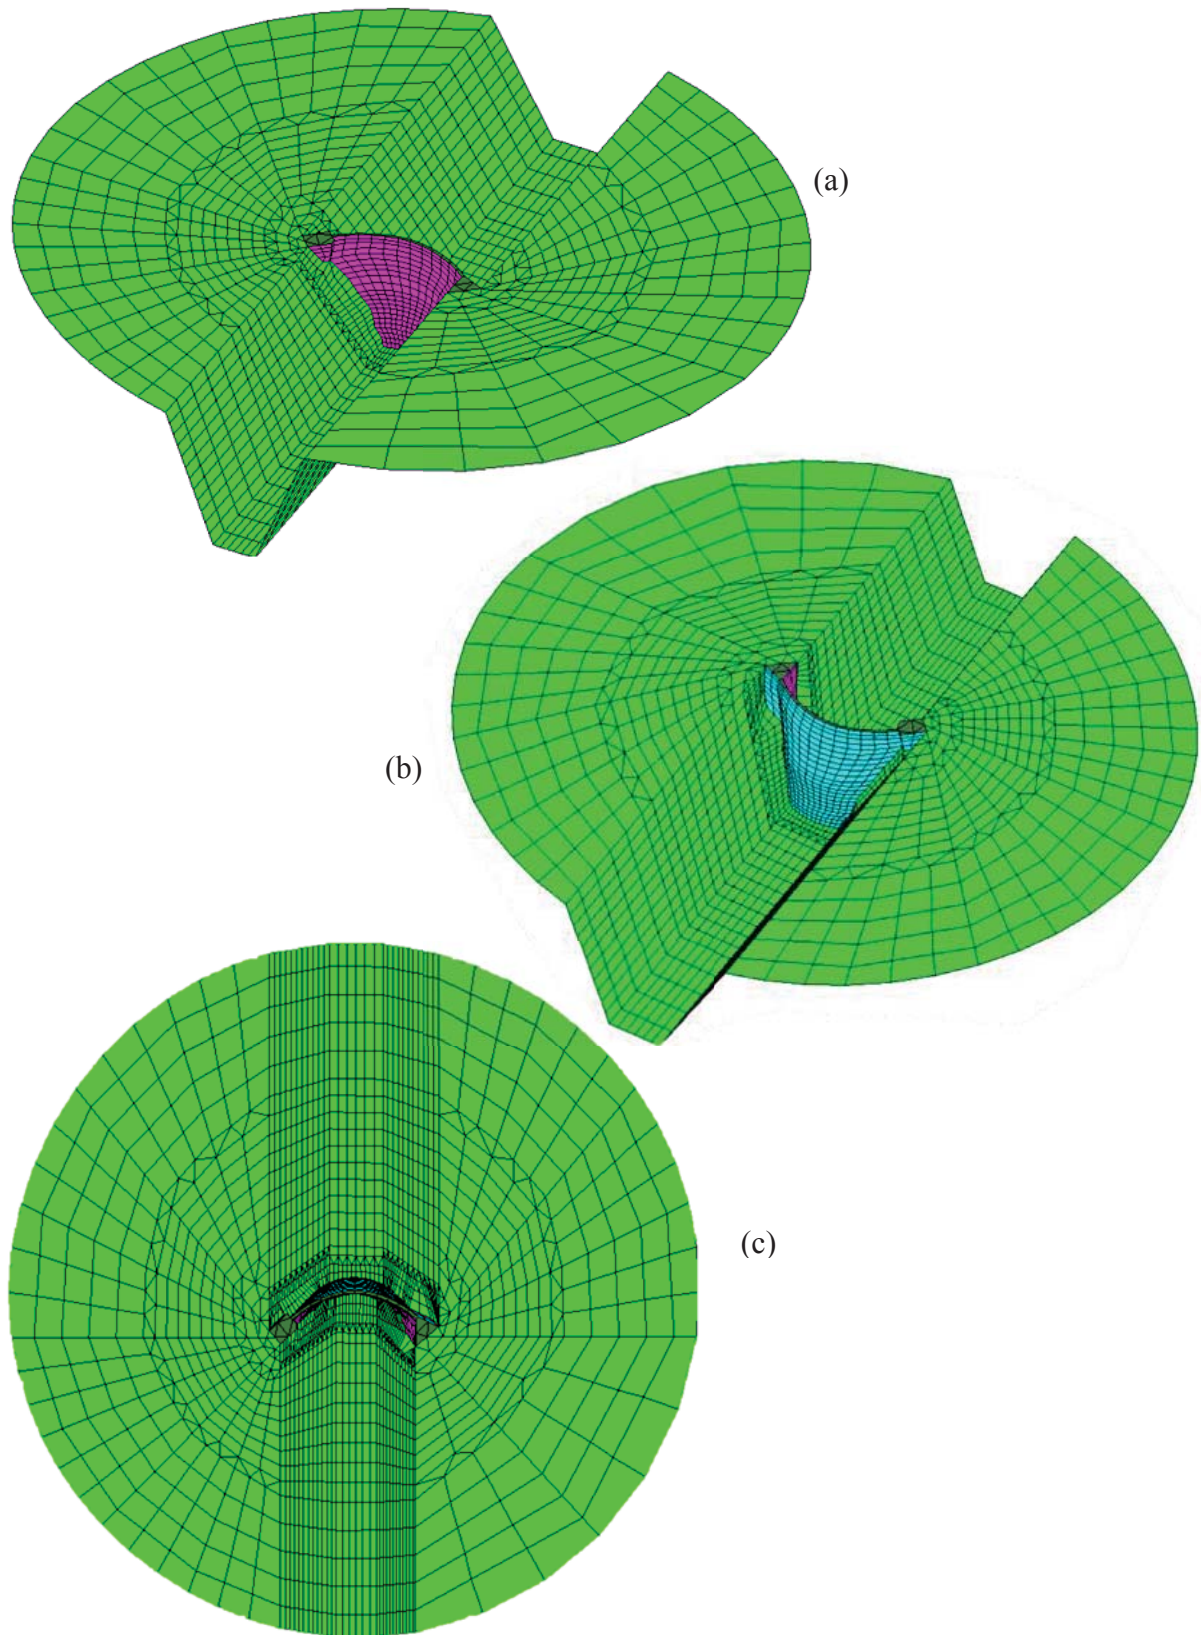

**Figure 4:** 3D mesh used for the BEM analysis of the dam wall. (a) Downstream side view, (b) up-stream side view and (c) top view.

BEM models	Number of nodes	Number of elements
Fixed base	3228	733
Compliant base. Prismatic canyon (R=240 m)	8168	2023
Compliant base. Topographic canyon (R=240 m)	10397	2739
Compliant base. Prismatic canyon (R=360 m)	10408	2631

Table 1: Number of nodes and elements in BEM models.

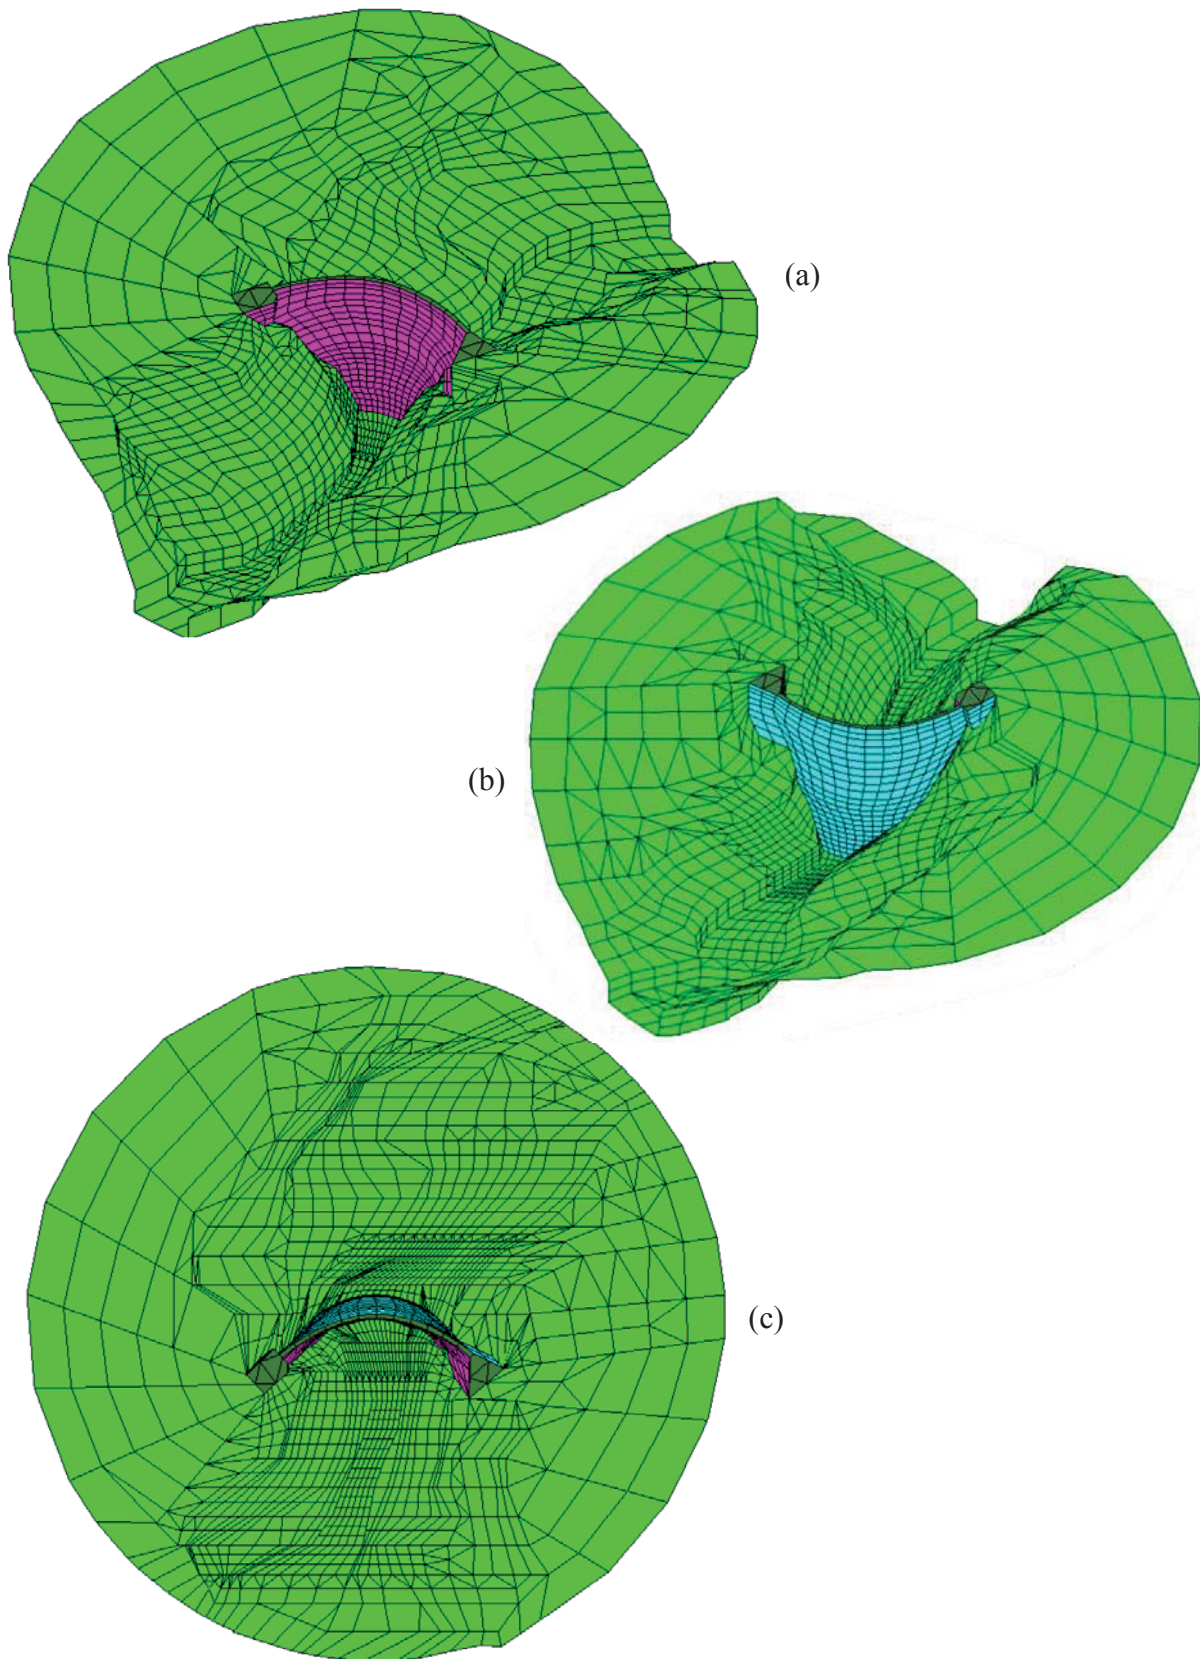

**Figure 5:** BE model, prismatic canyon. Extension of the free-field discretization: 240 m. (a) Downstream side view, (b) up-stream side view and (c) top view.

**Figure 6:** BE model, prismatic canyon. Extension of the free-field discretization: 360 m. (a) Downstream side view, (b) up-stream side view and (c) top view.

**Figure 7:** BE model. Approximation of the actual topography of the canyon. Extension of the free-field discretization: 240 m. (a) Downstream side view, (b) upstream side view and (c) top view.

The nodes studied are node 1, node 2 and node 3 which are located approximately at 1/4, 1/2 and 3/4 of the dam crest, measured from left to right abutment, respectively (Figure 8). Frequency response functions obtained by BE method in these nodes will be plotted for 4 cases: Fixed-base and compliant-base with different geometries (Figures 5, 6 and 7).

**Figure 8:** Nodes studied.

On the one hand, in the fixed-base analysis, a unit harmonic horizontal displacement along the up-stream and cross-stream direction was prescribed at the abutments and base of the dam wall (Figure 9.a) ; on the another, for the compliant analysis, the system is assumed to be impinged by seismic time-harmonic plane waves. For this analysis, it was assumed that the incident wave field consists solely of plane S waves propagating vertically with a horizontal up-stream and cross-stream free-field ground surface motion [7] (Figure 9.b).

**Figure 9:** Boundary conditions used in harmonic analyses. (a) Fixed and (b) compliant base.

As mentioned, the concrete dam wall is assumed to be viscoelastic solid with the following properties: density,  $\rho = 2300 \text{ kg/m}^3$ ; Poisson's ratio,  $\nu = 0.2$ ; shear modulus,  $G = 8167 \text{ MPa}$  and internal damping,  $\xi = 0.01$ ; the foundation rock material is also assumed to be viscoelastic media with a density,  $\rho = 2143 \text{ kg/m}^3$ ; Poisson's ratio,  $\nu = 0.2$ ; shear modulus,  $G = 12083 \text{ MPa}$  and internal damping,  $\xi = 0.01$  [1, 7].

### 3 ANALYSIS OF RESULTS

The first four mode shapes and natural vibration frequencies obtained with the finite element modal analysis (FEM) with the fixed-base model, together with the modes inferred from the harmonic analysis with the fixed-base model using boundary element method (BEM) are shown in Figure 9 and table 2, respectively.

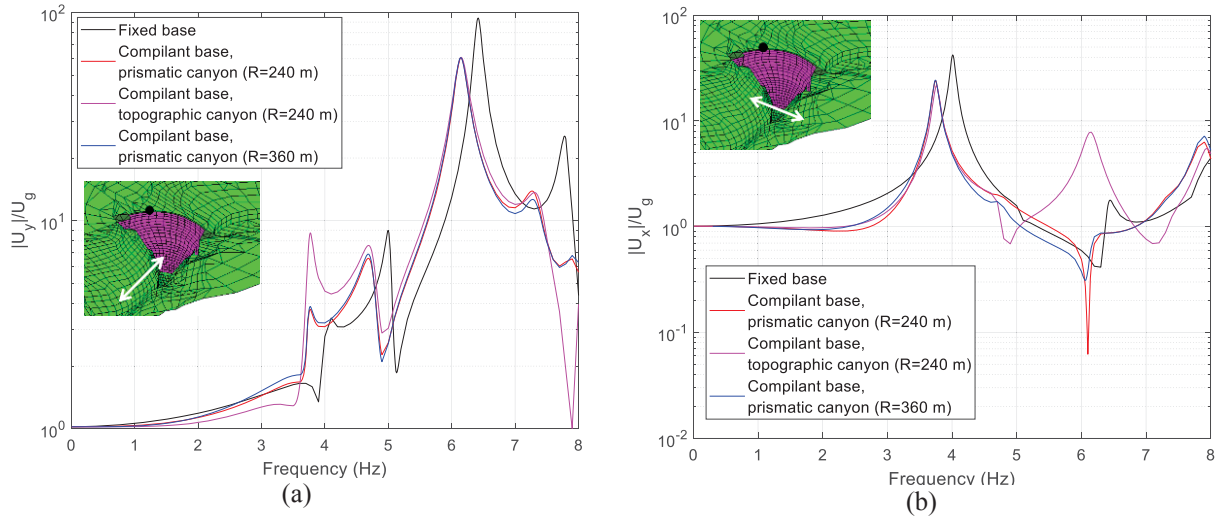

**Figure 9:** Mode shapes of vibration: (a) FEM ; (b) BEM.

Mode shapes	FEM	BEM
First mode	3,99 Hz	4,00 Hz
Second mode	4,99 Hz	5,00 Hz
Third mode	6,37 Hz	6,40 Hz
Fourth mode	7,80 Hz	7,80 Hz

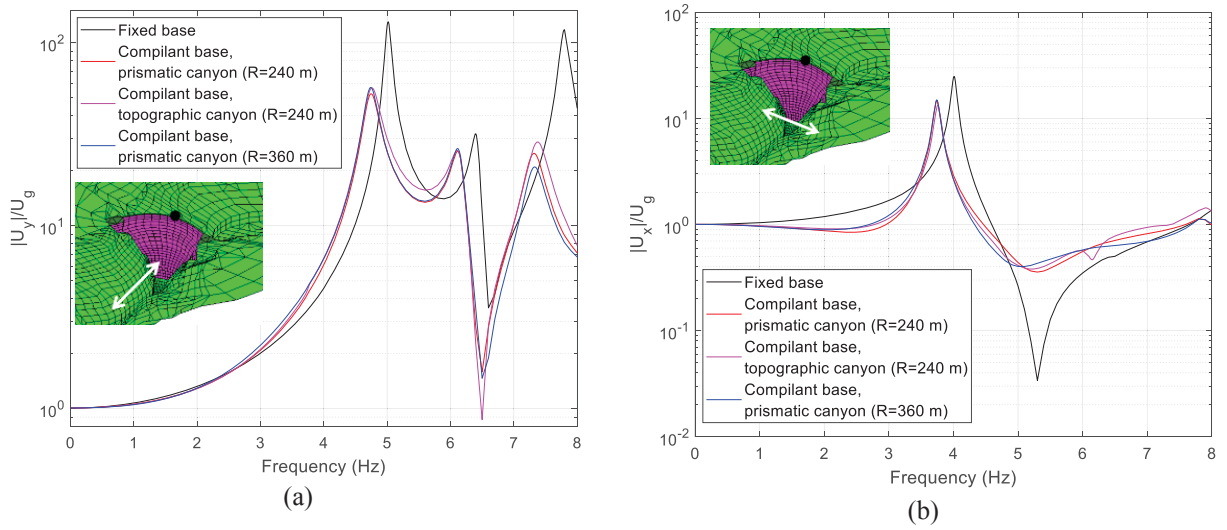

Table 2: Fundamental frequencies: FEM and BEM models.

As can be seen, a very good agreement is observed between the two sets of results, in terms of both mode shapes (Figure 8) and fundamental frequencies (table 2) which contributes to validate the BE wall mesh used below in the fixed and compliant-base harmonic analyses.

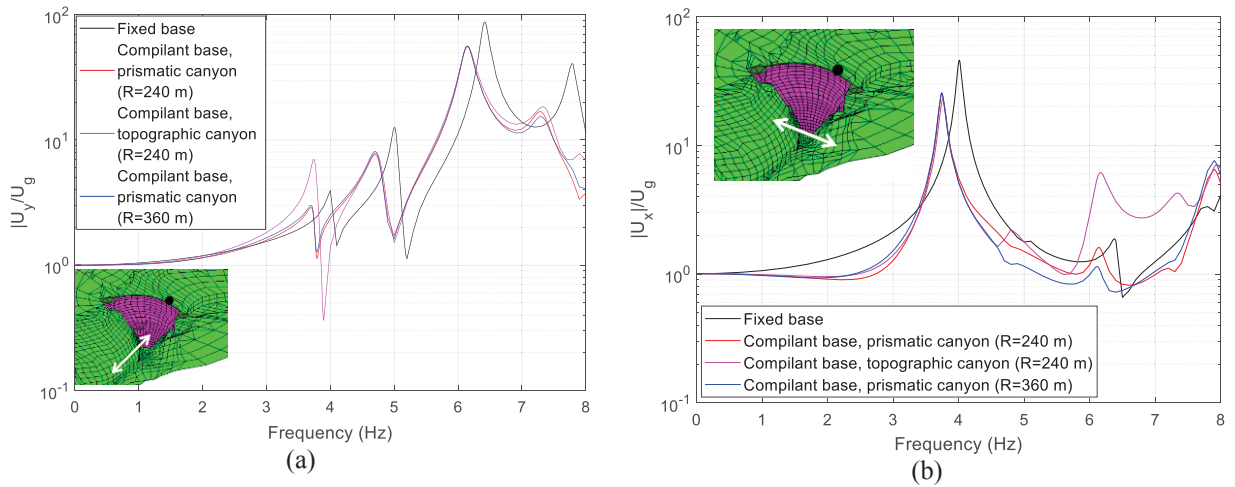

The frequency response functions computed for the fixed-base and compliant-base models with different geometries at the nodes studied are plotted in Figures 10 and 11.

**Figure 10:** FRFs. (a) Longitudinal and (b) transversal response of node 1.

**Figure 11:** FRFs. (a) Longitudinal and (b) transversal response of node 2.

**Figure 12:** FRFs. (a) Longitudinal and (b) transversal response of node 3.

BEM models	First frequency	Second frequency	Third frequency	Fourth frequency
Fixed base	4.01 Hz	5.00 Hz	6.44 Hz	7.80 Hz
Compilant base, prismatic canyon (R=240 m)	3.74 Hz	4.75 Hz	6.10 Hz	7.32 Hz
Compilant base, topographic canyon (R=240 m)	3.76Hz	4.76 Hz	6.14 Hz	7.38 Hz
Compilant base, prismatic canyon (R=360 m)	3.74 Hz	4.74 Hz	6.11 Hz	7.33 Hz

Table 3: Fundamental frequencies obtained with harmonic analyses.

As expected, the frequency-domain analyses carried out show that the soil—structure interaction has an important influence on the dynamic response of the dam wall both in amplitude and frequency (Figures 10, 11 and 12, table 3) due to damping character of the soil; as can be observed in table 4, the vibration frequencies on compliant base are between 4.5-6.5% lower than in fixed base.

Models	First frequency	Second frequency	Third frequency	Fourth frequency
Compilant base, prismatic canyon (R=240 m)	- 6.50%	- 5.00%	- 4.53%	- 6.15%
Compilant base, topographic canyon (R=240 m)	- 6.00%	- 4.80%	- 4.53%	- 5.38%
Compilant base, prismatic canyon (R=360 m)	- 6.50%	- 5.20%	- 4.53%	- 6.02%

Table 4: Fundamental frequencies reduction %. Compliant base versus to fixed base.

On the other hand, regarding the seismic response of the compliant-base models with different geometrical models of the canyon, it can be seen that while the response of the central node (Figure 11) is mostly unaffected by the level of accuracy of the representation of the topography of the area around the dam wall, the response computed for the most accurate geometrical model for the nodes placed at 1/4 (Figure 10) and 3/4 (Figure 12) of the length of the dam crest show a larger response of the first mode (which is mostly asymmetrical) for the upstream excitation (Figures 10.a and 12.a) and larger response of the third mode (which is mostly symmetrical) for the cross-stream excitation (Figures 10.b and 12.b). This is clearly due to the asymmetry of the topographical representation of the canyon, not present in the first two simplified models of the canyon.

#### 4 CONCLUSIONS

In this paper, a boundary element model for the dynamic analysis of coupled systems consisting of solid viscoelastic regions have been applied to the study of the dynamic response of a concrete arch dam taking into account soil-structure interaction.

The frequency-domain analyses carried out show that the soil—structure interaction has an important influence on the seismic response of the dam wall (the vibration frequencies on compliant base are up to 6.50% lower than in fixed base). It has also been found that the asymmetry of the canyon might affect significantly the seismic response of the dam wall.

In future studies, numerical models involving structure-soil-water interaction with different reservoir levels will be studied in order to analyze the influence of this interaction on the dam crest, moreover an experimental modal analysis is also planned in order to obtain information for the calibration of the numerical model.

### Abstract

*In the last few years, the ever-increasing computing power of personal computers has allowed to explore beyond the assumption of linear viscous-elastic behaviour usually made for foundation soils, even when subjected to strong seismic excitations. In this context, [Gaudio and Rampello \[1\]](#) performed a parametric study focusing on the seismic performance of massive caisson foundations supporting bridge piers subjected to strong one-directional earthquakes, capable of triggering the nonlinear and inelastic soil behaviour. 3D dynamic Finite Element (FE) analyses were performed twice in the time domain, once assuming the soil to behave as an elastic-plastic and once as a linear viscous-elastic medium: through the comparison of results, the observed reduction of inertial forces transmitted to the superstructure was mainly attributed to the energy dissipation occurring in the foundation soils, due to the attainment of their inelastic behaviour. These nonlinearities can be classified as “primary”, developing in the free-field soil, and “secondary”, resulting from the oscillating foundation [2]: these were not distinguished in the parametric study.*

*In this paper a step further is made, as the relative influence of the “primary” and “secondary” nonlinearities is evaluated. A simple 3-degree-of-freedom plane-strain model simulating the soil-foundation-bridge pier-deck system is subjected to the horizontal acceleration time histories computed at the depth of the foundation centroid from preliminary 1D inelastic ground response analyses performed in free-field conditions. The influence of “primary” nonlinearities is assessed by comparing these results with those obtained after applying seismic inputs coming from 1D nonlinear viscous-elastic free-field analyses. The comparison is performed in terms of some performance indexes, such as the deck drift and the bending moment acting at the base of the pier. A fair estimate of the influence of “secondary” nonlinearities is finally provided comparing the results obtained applying the 1D inelastic free-field motion with those computed in the 3D nonlinear dynamic FE analyses.*

## 1 INTRODUCTION

Role of soils on the seismic performance of superstructure such as buildings and bridges has been being explored with increasing accuracy for the last 50 years. However, its influence has been often condensed in the increase of flexibility of the soil-foundation-structure system seen as a whole and of the damping with respect to the fixed-base case, thanks to the introduction of the foundation-soil finite stiffness and of the geometric and material damping [3, 4]. This change in the dynamic properties is even more pronounced when the system is hit by high-intensity earthquakes, as a result of the decreasing shear modulus and growing damping ratio as a function of the shear strain experienced by the foundation soils during the seismic event. The increase of the period of the equivalent system can be easily evaluated even through analytical relationships, provided that at least a preliminary 1D ground response analysis is performed in free-field conditions via the Linear Equivalent (*LE*) method [5], so that the magnitude of the shear strain to be expected is properly evaluated. Although this approach allows the user to account for the nonlinear behaviour of foundation soils, it does not permit any evaluation of the effects of their inelastic behaviour, the latter implying the accumulation of permanent deformations until the end of the seismic shaking. Indeed, this aspect can strongly affect the seismic performance of structures subjected to strong ground motions and should be carefully assessed.

In the above-mentioned context, Gaudio and Rampello [1] recently performed a parametric study through 3D nonlinear dynamic FE analyses on caisson foundations of bridge piers subjected to strong ground motions, clearly showing that the influence of soil inelastic behaviour is to be considered when assessing their seismic performance, especially when the fundamental period of the whole soil-caisson-pier-deck system (i.e. considering lengthening of the period due to soil-structure interaction),  $T_{eq}$ , approaches the period of the free-field 1D soil column,  $T_0$ . They also discussed the influence of *Foundation Input Motion (FIM)* and compared it with that of irreversible soil behaviour. Although the study [1] provides some useful empirical relationships that can be used to get the overestimation of peak displacements and forces that is typically obtained when irreversible and hysteretic soil behaviour is neglected, as a function of the period ratio  $T_{eq}/T_0$  and of the significant duration of the earthquake,  $T_D^{inp}$  [6], it does not detail the contribution of the so-called “primary” and “secondary” soil nonlinearities (even if “nonlinearities” should be replaced with “plasticity” in this context, more properly). The term “primary” stands for the development of permanent deformations and dissipation of energy in the free-field soil column, whereas “secondary” indicates the same but caused by the oscillating foundation and by the structure as a whole.

In this paper, the relative influence of the primary and secondary nonlinearities is evaluated, following the work that can be found in [1]. Specifically, a 3-degree-of-freedom (3DoF) plane-strain model representing several soil-foundation-bridge pier-deck systems is subjected to the horizontal acceleration time histories computed at the depth of the foundation centroid from preliminary 1D inelastic free-field ground response analyses. The influence of “primary” nonlinearities is first assessed by comparing these results with those computed applying at the node representing the foundation the input motions retrieved from 1D nonlinear viscous-elastic free-field analyses. The comparison is performed in terms of the deck drift and the bending moment acting at the base of the pier. A fair estimate of the influence of “secondary” nonlinearities is then provided through the comparison of the results obtained applying the 1D inelastic free-field motion with those computed in the 3D nonlinear dynamic FE analyses in which the soil-foundation-pier-deck system is described. Although not rigorous, this procedure permits clearly understanding, for the cases at hand, of the relative contribution of soil far and close to the structure.

## 2 PROBLEM SETTING

The problem layout considered in the parametric study is depicted in Figure 1a. The transversal section of a bridge is considered, where the cylindrical caisson foundation of height  $H$  and diameter  $D$  is embedded in a 5-m-thick gravelly sand layer underlain by a 55-m-thick layer of silty clay, this being representative of an alluvial deposit. The infinitely-rigid bedrock is located at depth  $Z = 60$  m, where the seismic input motion is applied in the  $x$  direction in terms of horizontal acceleration time histories. Water table is placed at the interface between the sand and the clay layers ( $z_w = 5$  m), with a hydrostatic pore water pressure regime. The pier is modelled through a linear viscous-elastic Single-Degree-of-Freedom System (*SDoF*) characterized by a stiffness  $k_s$ , simulating the flexural stiffness of the pier, a damping ratio  $\xi_s = 5\%$  and a lumped mass  $m_s = m_{\text{deck}} + 0.5 \cdot m_{\text{pier}}$ , where  $m_{\text{deck}}$  and  $0.5 \cdot m_{\text{pier}}$  are the mass of the deck and of the upper half of the pier, respectively. The mass of the lower half of the pier is applied to the top of the caisson via a uniform distribution of vertical stresses  $\sigma_{z(0.5\text{pier})}$ .

Mechanical properties of the foundation soils are given in Table 1, where  $\gamma$  is the unit weight,  $c'$  and  $\phi'$  are the effective cohesion and the angle of shearing resistance,  $OCR$  is the overconsolidation ratio and  $k_0$  is the earth pressure coefficient at rest [7]. The profile assumed for the small-strain shear modulus  $G_0$  was obtained using the empirical relations proposed by Hardin and Richart [8] for the gravelly sand and by Rampello *et al.* [9] for the silty clay, and

Soil	$\gamma$ (kN/m <sup>3</sup> )	$c'$ (kPa)	$\phi'$ (°)	$OCR$ (-)	$k_0$ (-)	$G_0^{\text{rel}}$ (MPa)	$m$ (-)	$\gamma_{0.7}$ (%)	$E_{\text{ur}}^{\text{rel}}$ (MPa)	$\nu_{\text{ur}}$ (-)	$E_{50}^{\text{rel}}$ (MPa)	$E_{\text{oed}}^{\text{rel}}$ (MPa)

Table 2: Properties of the systems considered in the parametric study.

is plotted in [Figure 1b](#) together with that of *OCR*.

In the parametric study fourteen deck-pier-caisson-soil systems were considered, differing in caisson diameter ( $D = 8$  and  $12$  m), caisson slenderness ratio ( $H/D = 0.5$ ,  $1$  and  $2$ ), and pier height ( $h_s = 15$ ,  $30$  and  $60$  m). Here it is worth noting that some extreme cases were excluded as they were deemed not realistic (i.e. pier of height  $h_s = 15$  m over a  $24$ -m-deep caisson). Values of the pier flexural stiffness  $k_s$  and masses  $m_{\text{deck}}$ ,  $m_{\text{pier}}$  and  $m_s$  were selected to represent span lengths ranging between  $40$  and  $110$  m and to return fixed values of the safety factor against bearing capacity under static and pseudo-static conditions,  $F_{\text{sv}} = 5.5$  and  $F_{\text{se}} = 0.7$ , respectively. More details about this methodology are given in [\[11, 12\]](#); the main characteristics of the systems are reported in [Table 2](#).

### 3 FINITE ELEMENT MODELLING

The dynamic analyses were first performed using the FE code PLAXIS 3D [\[13\]](#) with the numerical domain shown in [Figure 2a](#) [\[1\]](#). Each analysis was performed twice, adopting two different constitutive models for foundation soils: the elastic-plastic constitutive model *Hardening Soil with Small-Strain Stiffness* (*HS small*, [\[14\]](#)) and a linear viscous-elastic model, the former with the mechanical parameters given in [Table 1](#), the latter with “mobilised” values of shear modulus  $G$  and of damping ratio  $\xi$  resulting from preliminary 1D free-field analyses carried out with the *LE* method. Here it is worth mentioning that the same curves reproducing shear modulus decay and damping ratio increase with the shear strain,  $G/G_0$  and  $\xi = f(\gamma)$ , were assumed in the 3D analyses with *HS small* and in the 1D free-field analyses with the *LE* method, namely that proposed by [Seed and Idriss](#) [\[15\]](#) for the sand and by [Vucetic and Dobry](#) [\[16\]](#) for the clay (plasticity index  $I_p = 25$  %). In the dynamic calculation phase, the systems were subjected to six different acceleration time histories, intense enough to trigger the bearing capacity of the caisson foundations: for the sake of brevity, only three of them are considered in the following ([Fig. 3a-b](#)).

Comparison of results permitted to better understand the role of soil plasticity on the seismic performance of the systems at hand. Albeit these analyses were useful in achieving the proposed objective, they did not allow to properly distinguish in between primary and secondary nonlinearities, as summarised in [Table 3](#). Therefore, a simplified plane-strain *3DoF*

Figure 2: (a) numerical domain modelled in Plaxis 3D; (b) 3DoF model (modified from [1]).

model was implemented in the FE code SAP2000 v.20 [17], where the three independent degrees of freedom are: the horizontal displacement of the foundation relative to the motion applied to the fixed end of the horizontal impedance  $\tilde{K}_{xx}$ ,  $u_{c,G}$ , the angle of caisson rigid rotation  $\theta$  and the flexural displacement of the pier column,  $u_{flex}$  (Fig. 2b). This model turned out to be reliable in reproducing the results obtained in the 3D FE linear viscous-elastic analyses, provided that the *FIM* is applied, that the dynamic impedance matrix is computed referring to the “mobilised” values of  $G$  and  $\xi$  and that the coupled terms  $\tilde{K}_{xr} = \tilde{K}_{rx}$  are considered [1]. This 3DoF model was also adopted to understand the relative influence of the “primary” and “secondary” soil nonlinearities. To this end, the free-field motion (*FFM*) computed at the depth of the caisson centroid,  $z = z_G$ , from preliminary 1D ground response analyses was applied at the fixed end of the pure-translational dynamic impedance,  $\tilde{K}_{xx}$ : following what already done for the 3D FE analyses, these free-field analyses were performed twice, once adopting *HS small* and once through the *LE* method, already implemented in the code MARTA [18] (Tab. 3). Albeit not being rigorous, this procedure permitted to catch the role of primary nonlinearities on the seismic performance of bridge piers over caisson foundations, as it will be clarified in the following section.

#### 4 1D FREE-FIELD GROUND RESPONSE ANALYSES

The input motions applied at the base of the 3DoF model were preliminary computed at

#	model	soil const. model	seismic input	nonlinearities
1	3D	elastic-plastic	bedrock at $z = Z$	$G/G_0$ and $\xi = f(\gamma)$ , primary, secondary
2	3D	linear viscous-elastic	bedrock at $z = Z$	$G/G_0$ and $\xi = f(\gamma)$
3	3DoF	nonlinear viscous-elastic	from 1D free-field analyses with <i>HS small</i> at $z = z_G$	$G/G_0$ and $\xi = f(\gamma)$ , primary
4	3DoF	nonlinear viscous-elastic	from 1D free-field analyses with nonlinear viscous-elastic model at $z = z_G$	$G/G_0$ and $\xi = f(\gamma)$

Table 3: FE analyses carried out to assess the influence of the nonlinear and irreversible soil behaviour.

Record	$F$ (-)	$a_{\max}^{\text{inp}}$ (g)	$I_A^{\text{inp}}$ (m/s)	$T_m^{\text{inp}}$ (s)	$T_D^{\text{inp}}$ (s)
Tolmezzo E-W	1.00	0.316	1.17	0.50	5.220
Assisi E-W	2.00	0.332	1.12	0.24	4.295
Adana E-W	1.05	0.292	1.17	0.62	12.990

Table 4: Parameters of the scaled seismic input motions.

the depth  $z = z_G = H/2$  of the caissons' centroid by performing the above-mentioned 1D ground response analyses in free-field conditions twice, once with the elastic-plastic *HS small* and once with the nonlinear viscous-elastic soil constitutive models. The analyses were carried out imposing at the base of the soil column ( $z = Z = 60$  m) six different high-intensity seismic inputs: for the sake of brevity, only three of them are considered in this paper, whose horizontal acceleration time histories and elastic acceleration spectra are plotted in Figure 3a and b, respectively. The main characteristics of these seismic inputs are listed in Table 4, where  $F$  is the amplification factor adopted to reach the desired level of Arias intensity,  $a_{\max}^{\text{inp}}$  is the peak horizontal acceleration,  $I_A^{\text{inp}}$  is the Arias intensity [19],  $T_m^{\text{inp}}$  is the mean period [20] and  $T_D^{\text{inp}}$  is the strong-motion duration. All the records are characterised by about the same  $I_A^{\text{inp}}$ : moreover, the Assisi record (second line) differs from the Tolmezzo one (first line) in its frequency content ( $T_m^{\text{inp}}$ ), having the same strong-motion duration, while the Adana record (third line) differs from Tolmezzo in  $T_D^{\text{inp}}$ , having about the same frequency content.

The average spectrum resulting from all six records is also plotted in Figure 3b for a damping ratio  $\xi = 5\%$  (equal to that of the bridge pier,  $\xi_s$ ), together with the one resulting from the Italian Building Code [21] for a return period  $T_R = 1424$  years, taken as a reference to check spectrum compatibility in the entire parametric study.

The inputs applied at the base of the *3DoF* models were extracted from the 1D soil column at the depth of the caissons' centroid, as represented in Figure 3c, where the soil column modelled in Plaxis 3D for the elastic-plastic analyses (*HS small*) is given. The results of the free-field ground response analyses are discussed in the following section.

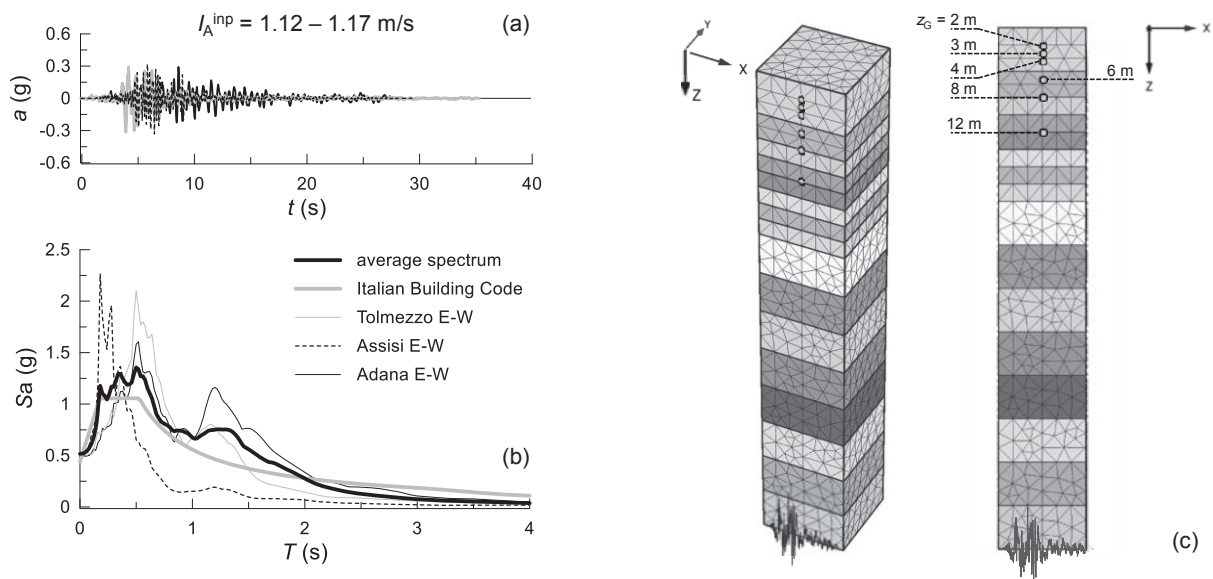

Figure 3: (a) Time histories and (b) elastic spectra of horizontal acceleration of the adopted input motions; (c) soil column modelled in Plaxis for the 1D ground response analysis with *HS small* and depths at which seismic outputs were extracted.

## 5 INFLUENCE OF PRIMARY SOIL NONLINEARITIES ON THE SEISMIC PERFORMANCE

The influence of primary soil nonlinearities was assessed by comparing the seismic performance obtained applying to the *3DoF* model the horizontal acceleration time histories computed at  $z = z_G = H/2$  in the elastic-plastic and the nonlinear viscous-elastic free-field analyses. Hence, a comparison of free-field results only is first made (§ 5.1); then, the seismic performance obtained with the *3DoF* model is assessed (§ 5.2).

### 5.1 Comparison of results in free-field conditions

A sample of results obtained for the soil column is given in Figure 4 referring to the Tolmezzo record, where profiles of the peak horizontal acceleration (a) and shear strain (b) are plotted, together with the contours of the plastic deviatoric strain  $\varepsilon_s^p$  obtained at the end of the earthquake when adopting the *HS small* constitutive model (elastic-plastic analyses, (c)). The deviatoric strain is the second invariant of the strain tensor, defined as follows:

$$\varepsilon_s = \sqrt{\frac{2}{3} \left[ \left( \varepsilon_{xx} - \frac{\varepsilon_v}{3} \right)^2 + \left( \varepsilon_{yy} - \frac{\varepsilon_v}{3} \right)^2 + \left( \varepsilon_{zz} - \frac{\varepsilon_v}{3} \right)^2 + \frac{1}{2} (\gamma_{xy}^2 + \gamma_{yz}^2 + \gamma_{zx}^2) \right]} \quad (1)$$

where  $\varepsilon_{ii}$  and  $\gamma_{ij}$ , for  $i \neq j$  and  $i, j = x, y, z$  are the components of the strain tensor along the three cartesian directions and  $\varepsilon_v = \varepsilon_{xx} + \varepsilon_{yy} + \varepsilon_{zz}$  is the volumetric strain.

The profile of peak horizontal acceleration (Fig. 4a) clearly shows almost overlapping elastic and elastic-plastic profiles from the base of the soil column ( $z = Z = 60$  m) up to a depth  $z \approx 17.5$  m: in this range of depths both constitutive assumptions predict a slight reduction of the peak acceleration with respect to the input one ( $a_{\max}^{\text{inp}} = 0.316$  g). This result is consistent with what observed for the peak shear strain  $\gamma_{\max}$ : indeed, similar trends are computed, with slightly higher  $\gamma_{\max}$  computed when adopting the nonlinear viscous-elastic soil model. Both analyses provide the same maximum peak shear strain  $\gamma_{\max} \approx 0.3\%$  at depth  $z \approx 17.5$  m, above

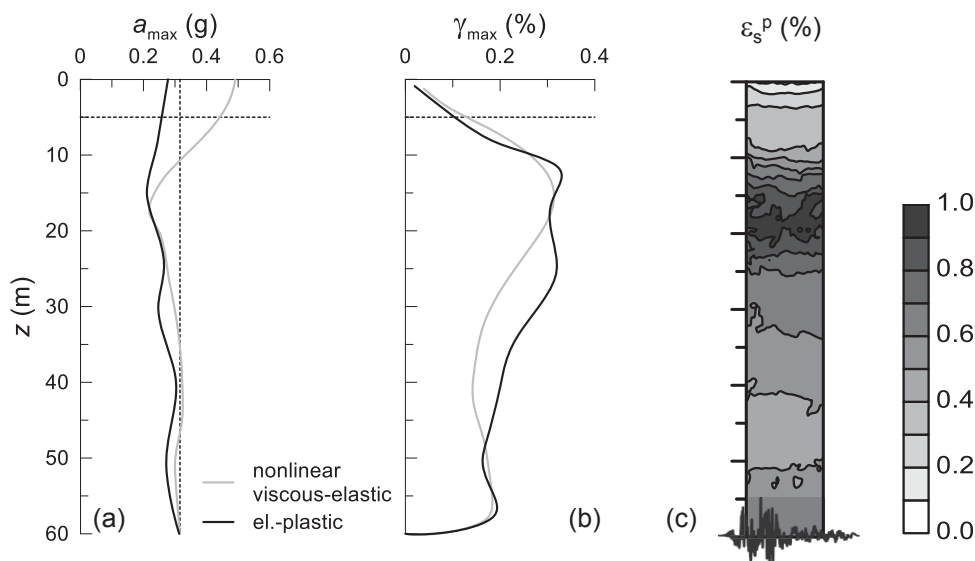

Figure 4: Comparison of 1D free-field ground response analyses when applying the Tolmezzo record: (a) peak acceleration; (b) peak shear strain; (c) contours of the plastic deviatoric strain at the end of the seismic shaking.

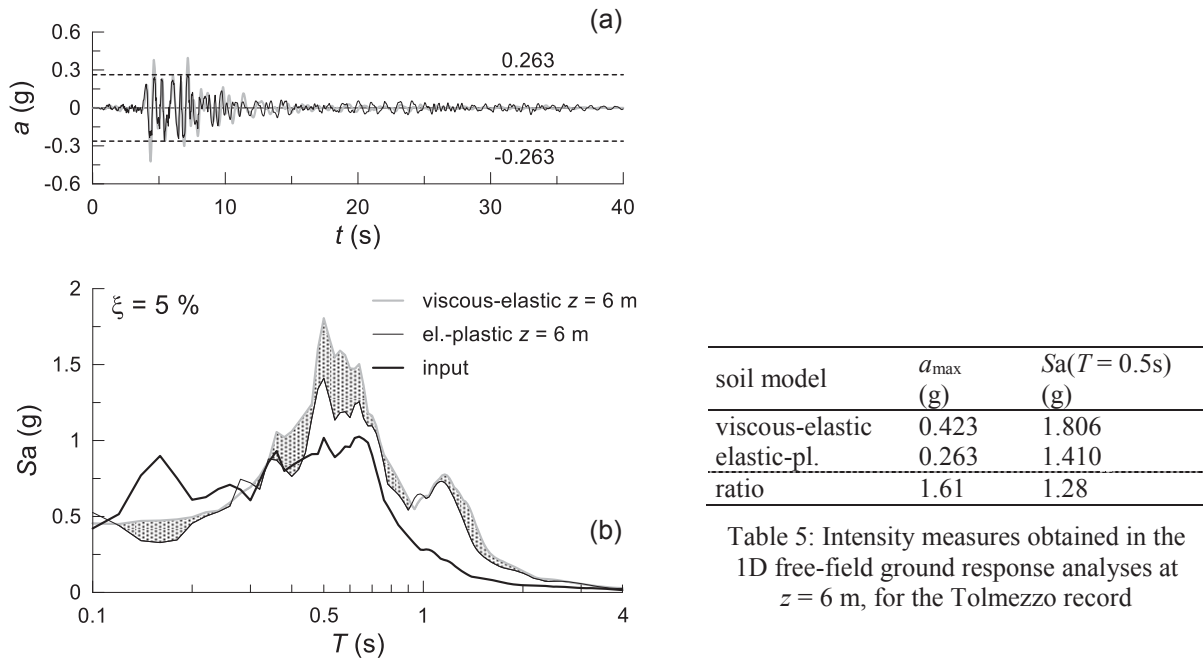

Figure 5: a) Time histories and (b) elastic spectra of horizontal accelerations computed at depth  $z = 6$  m in the viscous-elastic and elastic-plastic 1D free-field ground response analyses, together with the Tolmezzo record applied at the base of the column.

which shear strains still go overlapping with the two models. Due to this high distress experienced by the soil, peak horizontal accelerations  $a_{\max}$  start diverging when approaching the ground surface, with an almost constant peak acceleration in the elastic-plastic analyses ( $a_{\max} \approx 0.28g$  at  $z = 0$ ) whereas a strong amplification of motion is predicted by the elastic analysis ( $a_{\max} \approx 0.50g$  at  $z = 0$ ). This result may be attributed to the nonlinear and irreversible behaviour of foundation soils, mostly triggered at  $z \approx 20$  m, where dissipation of energy occurs, as it is clearly shown by the contours of plastic deviatoric strain  $\varepsilon_s^p$  plotted in Figure 4c, that attains its maximum value of about 1% at the end of the seismic shaking.

The influence of soil dissipating energy introduced by the seismic record on the free-field motion is shown in Figure 5 as well, where the horizontal acceleration time histories (a) and elastic acceleration spectra (b) computed at depth  $z = 6$  m are plotted for the Tolmezzo record. These results are the input motions applied at the node representing the foundation in the 3DoF model when caisson foundations with  $D = 12$  m and  $H/D = 1$  (i.e.  $z_G = 6$  m) are considered. The decrease of horizontal accelerations can be recognised in Figure 5a, where the time history computed with *HS small* shows a cut-off at  $a_{\max} = 0.263$  g, while that obtained with the linear viscous-elastic model attain its peak value  $a_{\max} = 0.423$  g.

Energy dissipation caused by irreversible soil behaviour turned out to be mainly located around the eigenperiods of the free-field soil column, provided that they are effectively activated by the frequency content of the seismic input. Shaded area plotted in Figure 5b indicates the range of periods where elastic acceleration spectrum obtained with the nonlinear viscous-elastic constitutive model is higher than the elastic-plastic one, this pointing out where dissipation of energy occurs. Main reduction of amplitude is located at  $T = 0.5$  s, this being the second eigenperiod of the soil column; less-intense reduction is observed close to  $T = T_0 \approx 1.0$  s, that is the fundamental period of the soil column.

A summary of the obtained values of  $a_{\max}$  and  $Sa(T = 0.5$  s) is given in Table 5.

## 5.2 Seismic performance of the system

The influence of primary nonlinearities on the seismic performance of the whole system was evaluated through the comparison of results obtained applying at the base of the *3DoF* model the free-field motions computed with the *HS small* and the nonlinear viscous-elastic soil models (Fig. 2b). With the three above-mentioned records (Tab. 4) and the fourteen systems considered in the parametric study (Tab. 2), 42 linear dynamic analyses were performed twice in the time domain, this returning a total amount of 84 analyses. A comparison of results is given in Figure 6, where the time histories of deck drift  $u_{rel}$  and bending moment acting at the pier base  $M_s$  are plotted, for the system with  $D = 12$  m,  $H/D = 1$  and  $h_s = 15$  m, subjected to the free-field motions shown in Figure 5a. As it could have been anticipated from the free-field results, peak values  $u_{rel, max}$  and  $M_{s, max}$ , here assumed as seismic performance indexes, attain lower values when considering elastic-plastic soil behaviour. Specifically, an overestimation of about 20% is computed when ignoring soil plasticity, as summarised in Table 6, whereas a quite similar frequency content is obtained for both time histories. Therefore, primary nonlinearities do affect the seismic performance of the system. This contribution is compared to secondary nonlinearities in the following section.

## 6 INFLUENCE OF SECONDARY SOIL NONLINEARITIES ON THE SEISMIC PERFORMANCE

The influence of secondary soil nonlinearities was finally assessed comparing the seismic performance indexes  $u_{rel, max}$  and  $M_{s, max}$  obtained in the proper 3D elastic-plastic analyses of the whole system carried out through the Plaxis numerical model (Fig. 2a and first line of Tab. 3) with the relevant results computed through the *3DoF* model when applying the elastic-plastic (i.e. *HS small*, third line of Tab. 3) 1D free-field motion. Figure 7 shows that the vast majority of results lay above the 1:1 line for both the deck drift (a) and the bending moment at the pier base (b), this indicating that soil irreversible strains developing close to the oscillating foundation during the seismic event play a remarkable role in improving the seis-

input from	$u_{rel, max}$ (m)	$M_{s, max}$ (MN·m)
viscous-elastic 1D	0.166	267.49
elastic-pl. 1D	0.134	220.40
ratio	1.24	1.21

Table 6: Seismic performance indexes computed for the system with  $D = 12$  m,  $H/D = 1$  and  $h_s = 15$  m, Tolmezzo record

Figure 6: Time histories of (a) deck drift and (b) bending moment computed for the system with  $D = 12$  m,  $H/D = 1$  and  $h_s = 15$  m through the *3DoF* model by applying at  $z_G$  the acceleration time histories computed with the viscous-elastic and elastic-plastic 1D free-field ground response analyses.

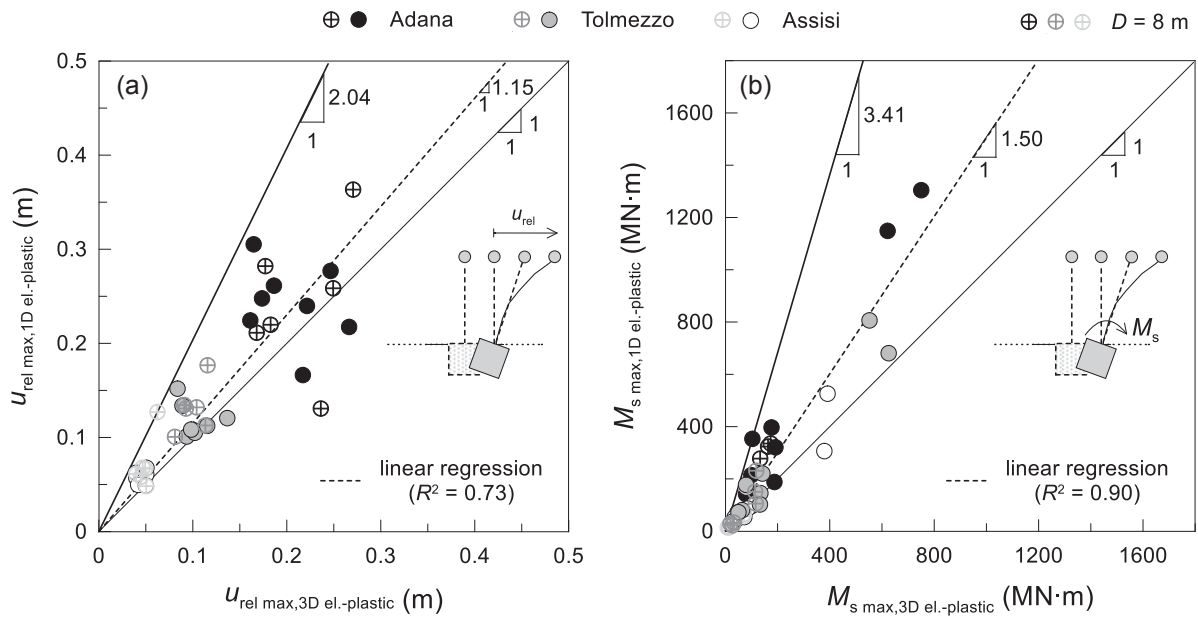

Figure 7: Comparison of results of the 3D elastic-plastic analyses of the whole system with those computed with the 3DoF model applying as input motion the 1D elastic-plastic free-field motion: peak values of (a) deck drift and (b) bending moment.

mic performance of the systems at hand, together with some kinematic interaction effects. In order to quantify the average overestimation of the peak values  $u_{rel, max}$  and  $M_{s, max}$  when performing the analyses with the 3DoF model subjected to the 1D elastic-plastic free-field motion, the slope of a standard linear regression was computed. Values equal to 1.15 and 1.50 were obtained for the deck drift and the bending moment, respectively, while a maximum overestimation of about 2.0 and 3.4 times was obtained, this clearly showing that the influence of secondary soil nonlinearities is stronger in reducing the inertial forces transmitted to the superstructure than the displacements. The role of the applied seismic inputs and of the caisson diameter on the contribution of secondary nonlinearities is not clear enough to draw any conclusion.

Graphs similar to those commented above are given in Figure 8, where the seismic performance computed in the 3D elastic-plastic analyses of the whole system is compared with the one obtained applying the nonlinear viscous-elastic 1D free-field motion to the base of the 3DoF model. As expected, higher slopes are obtained in Figure 8, as now the results include both the effects of primary and secondary nonlinearities: specifically, slopes equal to 1.25 and 1.63 were obtained for  $u_{rel, max}$  and  $M_{s, max}$ , with a maximum overestimation of about 2.73 and 3.87, respectively. The ratio between the slopes of linear regressions shown in Figures 7 and 8 allows to get a quick estimate of the relative influence of the primary and secondary soil nonlinearities: with reference to the average overestimation, about the same ratio is obtained for the deck drift and the bending moment, equal to about 9% ( $1.25/1.15 \approx 1.63/1.50 \approx 1.09$ ). This result suggests that, on average, neglecting primary nonlinearities would imply overestimating the peak values of the deck drift and bending moment of about 9%, whereas disregarding secondary nonlinearities would entail overestimating the seismic performance indexes of about 15 and 50%, respectively for  $u_{rel, max}$  and  $M_{s, max}$ , this proving the bigger role of soil plasticity developed close to the oscillating foundation than the one already triggered in free-field conditions for the cases at hand.

## 7 CONCLUSIONS

In this paper, the influence of irreversible and hysteretic soil behaviour occurring far (primary) and close (secondary) to oscillating caisson foundations supporting bridge piers has been assessed. To this end, free-field motion acting at the depth of the caisson centroids has been evaluated through 1D nonlinear viscous-elastic and elastic-plastic ground response analyses performed applying strong ground motions, capable of activating plastic soil behaviour. Then, the computed acceleration time histories have been applied to the node representing the soil-caisson system in a simple plain-strain 3-degree-of-freedom linear viscous-elastic structural model. The results have been compared with those obtained from a parametric study carried out on the whole soil-caisson-pier-deck system through 3D nonlinear dynamic FE analyses, using the peak deck drift and the bending moment at the base of the pier as performance indexes.

The comparison clearly indicates that, as it could be anticipated, primary soil nonlinearities imply a reduction of both  $u_{rel,max}$  and  $M_{s,max}$ , but only of about 9%, which might be deemed negligible. Conversely, the role of secondary nonlinearities is more pronounced, as this entailed a reduction approaching 15% for the deck drift and even 50% for the bending moment, this clearly indicating the major role of irreversible and hysteretic soil behaviour developing close to the foundation when hit by strong earthquakes.

Two main limitations arise in the study: first, there is the underlying assumption for which the effects of primary and secondary soil nonlinearities can be added. Clearly, this is a strong approximation, as in the inelastic regime the superposition principle does not hold: nonetheless, the discussed results may still shed some light on the relative influence of primary and secondary soil nonlinearities. Second, analyses may need some extension in terms of amount of systems and seismic inputs to be adopted, so as to make the study gain more generality and applicability to cases that have not been directly considered in the analyses, although the discussed results can be deemed suitable to soils whose stiffness linearly increases with depth. However, adopted systems and records already cover a wide range of cases typically encountered in the common practice and are representative of a large variety of input characteristics.

### Abstract

*Many bridges in earthquake-prone countries cross waterways and have foundations in riverbeds, and thus are exposed to flood, which may cause scour and a change of the bridge dynamics. The present study illustrates a modeling strategy for investigating numerically the influence of scour on the dynamic behaviour of bridges with scoured shallow foundations. The proposed strategy is based on the evaluation of the impedance functions of a massless rigid foundation resting on an elastic half-space under increasing depths of scour. The derived impedance functions are used to evaluate the effects of scour on the dynamic behaviour of a Soil-Foundation-Structure system representative of a bridge pier. In particular, the changes in the fundamental vibration period due to scour are investigated. The results of the study can be used for developing vibration-based scour detection techniques and for investigating the seismic response of scoured bridges.*

## 1 INTRODUCTION

Scour is the first cause of bridge failure worldwide [1-3], inducing not only traffic disruption but also significant socio-economic losses and fatalities [4-6]. Bridge scour is the erosion of sediments around bridge piers and abutments due to flowing water. Scour can be classified into natural, contraction and local scour, being the latter the most critical one. Particularly, local scour is formed due to local features, such as bridge piers and abutments, that obstruct the flow, leading to increased local flow velocities and turbulence levels that result in vortices and thus in local sediment movements and erosion around underwater foundations [7]. Scour may cause a significant loss of foundation carrying capacity [8, 9] and a reduction of the stiffness of bridges [10-16]. A great number of bridges worldwide, such as masonry-arch bridges, has shallow foundations that are more vulnerable to scour in comparison with those with deep foundations. Interestingly, the majority of the studies in the literature focus on the effects of scour on bridges with deep foundations, whereas studies related to bridges with shallow foundations are quite limited. Only recently, some research efforts have aimed at filling this knowledge gap [17-19].

Scour causes a change of the global stiffness of bridges, and thus a different response to dynamic loadings, such as earthquakes. In particular, scour can alter dramatically both the kinematic and the inertial soil-structure interaction, resulting in a reduction of the fundamental vibration frequency. There are several studies about the combined effect of scour and earthquake hazard on the dynamic properties of bridges [20-22], however most of them focus on bridges with deep foundations. To account for soil-foundation-structure (SFS) interaction effects, the sub-structure approach is usually employed, simulating the soil-foundation system in inertial interaction analyses through impedance functions [23-25]. These functions represent the frequency dependent stiffness and damping characteristics of soil-foundation system and govern relationships between forces and displacements of the compliant restraints at the foundation level. To the author's knowledge, only Guo [18] investigated the seismic response of bridges with scoured shallow foundations. Specifically, the foundation impedance functions were calculated under scour hazard, which led to a reduction of the foundation stiffness and radiation damping. It was found that scour reduces seismic force demands but may increase the displacement demands. Given the existence of a great number of bridge footings on shallow foundations in earthquake-prone countries and the current frequent occurrence of extreme weather events, further research on the effects of scour on the dynamic response of bridges is imperative.

This study investigates numerically the impact of scour on the dynamic response of bridges with shallow foundations. For this purpose, the case of a massless rigid strip foundation resting on a homogenous elastic half-space is modelled in Abaqus [26] under various scour scenarios to estimate the impedance functions of the soil-foundation system. Subsequently, the derived impedance functions are used to evaluate the dynamic behavior of a SFS systems, representative of a bridge pier, with particular focus on the fundamental vibration frequency.

## 2 NUMERICAL ESTIMATION OF FOUNDATIONS IMPEDANCES

In this section, a massless rigid strip foundation resting on a homogenous elastic soil domain is investigated. For the sake of simplification, a plane-strain problem assumption is made, based on taking into account the aspect ratios of masonry bridge's piers characterized by a slender rectangular shape. The model developed in Abaqus is firstly validated with numerical analytical solutions provided by Hryniewicz [23] and then adopted for the estimation of the impedance functions considering various scour profiles.

## 2.1 Finite element model

The modelling strategy developed in Abaqus for the estimation of impedance functions of the studied strip foundation is described in this subsection. The impedance functions can be expressed in non-dimensional form as a function of the non-dimensional frequency  $a_0 = \frac{\omega b_f}{V_s}$ , where  $\omega$  is the circular frequency of the excitation,  $b_f$  the half width of the foundation, and  $V_s$  the shear wave velocity.

The dimensions of the finite soil domain are assumed to be 125 x 62.5 m, while infinite elements are placed at the boundaries in order to satisfy the radiation condition preventing wave reflections (Figure 1i). These infinite elements are long strips with width equal to the half width of the soil domain, i.e. 62.5 m. Since a plane-strain assumption is made, the soil domain consists of four node plane-strain elements (CPE4), whereas the boundaries consists of plane-strain solid continuum infinite elements (CINPE4). The soil is characterized by a Young modulus ( $E$ ), Poisson's ratio ( $\nu$ ) and density ( $\rho$ ) equal to 162.41 MPa, 0.25 and 1600 kg/m<sup>3</sup>, respectively. The rigid strip foundation with width  $2b_f = 1$  m is simulated through a rigid-body constrain applied to the set of nodes belonging to the soil-foundation interface (at the ground surface). Considering that the estimated impedance functions are presented in a non-dimensional form, the selected values for the characteristics of the soil and foundation do not affect the results but are herein indicated because they have to comply with the adopted mesh for convergence issues. Indeed, in order to accurately capture the wave propagation, the mesh size of the soil domain should satisfy the following relation [27, 28]:

$$l_{max} \leq \frac{\lambda_{min}}{10} \leq \frac{V_{s,min}}{10 f_{max}} \quad (1)$$

where  $l_{max}$  is the maximum element size,  $\lambda_{min}$  is the shear wavelength and  $f_{max}$  is the maximum frequency of interest, which, for seismic applications, is typically within the range 0-15 Hz. For a given element size, the maximum dimensionless excitation frequency  $a_0$  satisfies:

$$a_0 \leq \frac{2\pi b_f}{10 l_{max}} \quad (2)$$

It is worth noting that a 1% damping ratio is added with a Rayleigh model to the soil domain in order to lessen the numerical fluctuation of the results. Considering above requirements, a refined mesh around the foundation is employed. Specifically, a square mesh 0.005 x 0.005 (m) and 0.025 x 0.025 (m) is used nearby the left and right sides of the foundation, respectively. The different mesh sizes at each part of the foundation aim at reducing the computational cost and facilitating the removal of elements at the next stages for the various scour simulations (see Section 2.4.). In the rest of the soil domain, a bias mesh towards to the boundaries is used with maximum element size  $l_{max} = 0.3$  m.

## 2.2 Methodology

The impedance functions are estimated by means of steady-state analyses by applying harmonic unit amplitude displacements at the centroid of the foundation (master node) and by measuring the corresponding harmonic reaction forces (Figure 1ii). The harmonic motion of the master node can be expressed with the following equation:

$$\begin{bmatrix} P(\omega) \\ Q(\omega) \\ M(\omega)/b_f \end{bmatrix} = \begin{bmatrix} k_{zz} + id_{zz} & 0 & 0 \\ 0 & k_{xx} + id_{xx} & k_{xr_y} + id_{xr_y} \\ 0 & k_{xr_y} + id_{xr_y} & k_{r_y r_y} + id_{r_y r_y} \end{bmatrix} \begin{bmatrix} w_0(\omega) \\ u_0(\omega) \\ \varphi_0(\omega)b_f \end{bmatrix} \quad (3)$$

where  $w_0$ ,  $u_0$  are the displacement amplitudes along the  $z$  and  $x$  directions, respectively,  $\varphi_0$  is the rotation amplitude, and  $k_{ij}$ ,  $d_{ij}=c_{ij}\omega$  are frequency-dependent quantities describing the real and the imaginary parts of the impedance functions, respectively, for the foundation response in the  $i$ -th direction due to the excitation in the  $j$ -th direction. Figure 2 illustrates forces and displacements along the various directions. The coefficients  $k_{ij}$  and  $d_{ij}$  evaluated numerically are presented as a function of the dimensionless frequency  $a_0$  and compared with the analytical estimates obtained by Hryniewicz [23]. This procedure will be also repeated for two scour layouts, characterized by different geometries (see Section 2.4.).

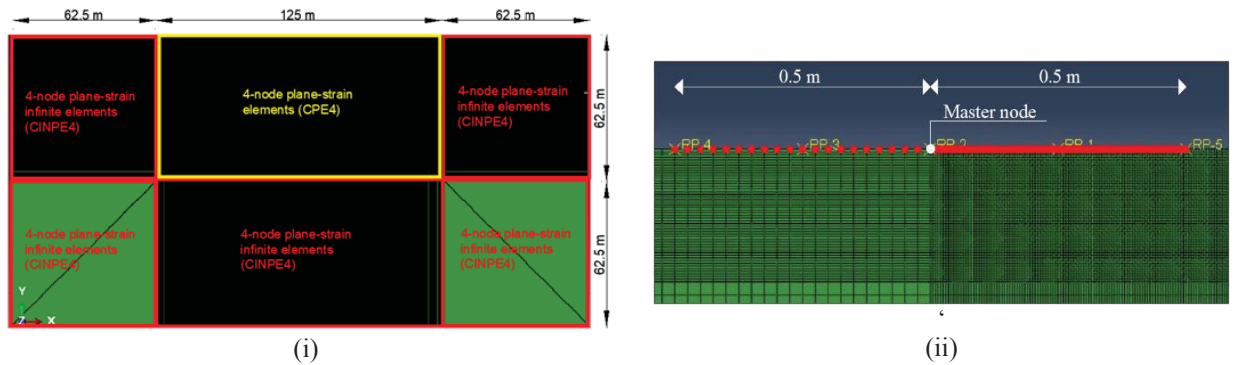

Figure 1: (i) FE model of the soil domain with infinite elements at boundaries, (ii) Rigid-body constraint used to simulate the massless rigid strip foundation.

Figure 2: (i) Forces and (ii) displacements of the strip foundation.

### 2.3 Validation of numerical model

In this subsection, the previously described numerical model is validated by comparing the derived impedance functions with those obtained by Hryniewicz [23]. It is noteworthy that in Hryniewicz [23] the coupling between the horizontal and rotational response of the foundation is neglected (i.e.  $k_{xr_y} = 0$ ,  $d_{xr_y} = 0$ ). However, this effect is expected to be not significant and for this reason in the numerical study the rotation of the master node is restrained when a unit horizontal displacement is applied and vice-versa. The harmonic analyses are carried out for frequencies in the range between 3.2 Hz and 200 Hz, corresponding to values of the dimensionless frequency  $a_0$  between 0.05 and 3.11. The derived impedance functions (NS-IC)

are depicted and compared with Hryniewicz's ones in Figure 3. The acronym NS stands for the case of "No Scour".

In general, the derived real and imaginary parts of the impedance functions converge with the analytically estimated ones. Nevertheless, some differences are observed for the real part of the rotational behaviour ( $k_{r_y r_y}$ ), which may be due to the approximation introduced by Hryniewicz [23] for deriving the problem solution. As mentioned before, the maximum element size of the finite soil domain is  $l_{max} = 0.3$  m, which, according to Eq. 2, leads to a maximum dimensionless frequency  $a_0 = 1.05$ . However, the application of a biased mesh around the foundation with element size significantly smaller than  $l_{max}$  results in a satisfactory agreement between the derived and analytical data also for higher frequencies (up to  $a_{0,max} = 3.11$ ).

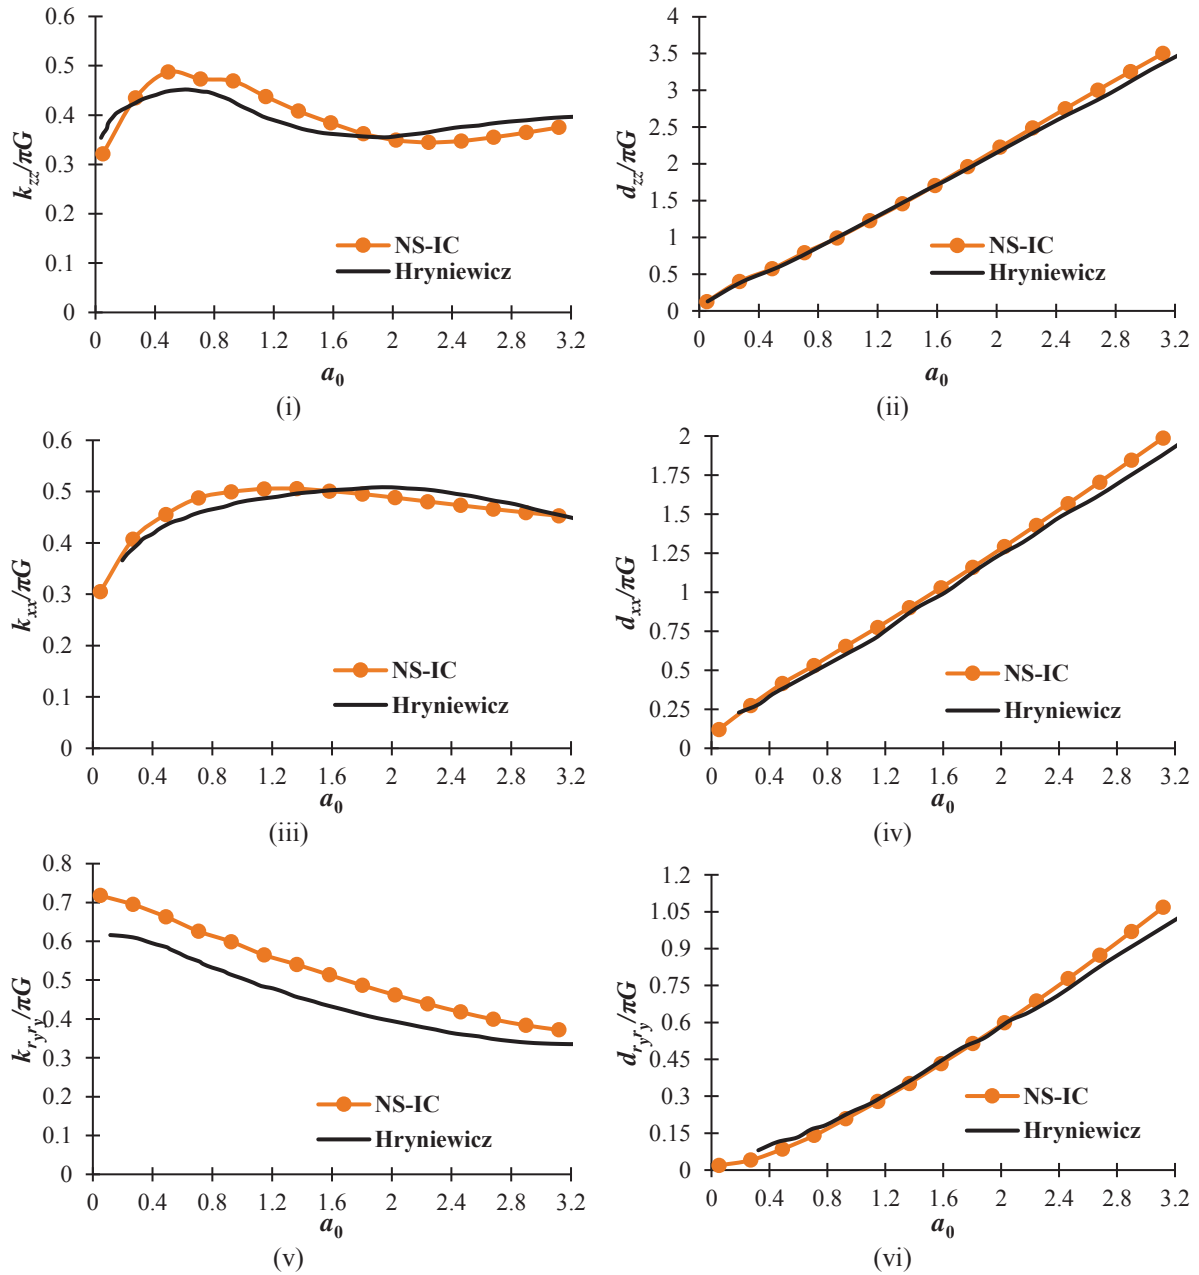

Figure 3: Comparisons of impedance functions obtained numerically (NS-IC) with those developed by Hryniewicz (i)  $k_{zz}$ , (ii)  $d_{zz}$ , (iii)  $k_{xx}$ , (iv)  $d_{xx}$ , (v)  $k_{r_y r_y}$ , (vi)  $d_{r_y r_y}$ .

## 2.4 Impact of scour on the foundation impedances

This subsection investigates the changes of the impedance functions of the foundation due to scour. Specifically, two triangular shaped scour scenarios with different widths and depths are considered, corresponding to one fourth (denoted as TS1/4) and three eighth (denoted as TS3/8) of the width of the foundation subjected to scour (Figure 4), respectively. Moreover, the upstream scour hole slope is assumed equal to  $\varphi=30^\circ$ , whereas the downstream scour slope is approximately half of the upstream slope [29].

The impedance functions of the foundation under the various scour scenarios are derived by removing the corresponding finite elements from the soil domain beneath the foundation and rerunning the harmonic analyses. It must be mentioned that the results are obtained by taking the coupling phenomenon between the horizontal and rotation response of the foundation into account (Figure 5). In general, it can be noticed that increasing the scour hole dimensions leads to a reduction of both real and imaginary components of the impedance functions for low frequencies. On the other hand, for high values of  $\alpha_0$ , increasing the scour depth and width results in an increase of the real part of the impedance functions. Moreover, it is remarkable that the values of the vertical real component ( $k_{zz}$ ) are higher than the case of no scour for higher frequencies.

Figure 4: Geometry of the 3 different scour hole scenarios investigated.

## 3 IMPACT OF SCOUR ON FUNDAMENTAL VIBRATION FREQUENCY OF A SFS SYSTEM

The foundation impedance functions for various scour scenarios estimated in Section 2, are herein used to investigate the impact of scour on the fundamental vibration frequency of a SFS system, representative of a bridge pier. Initially, the formulation of the dynamic problem is presented, and then the fundamental vibration frequency of the SFS system is calculated solving the eigenvalue problem for different levels of scour.

### 3.1 Problem formulation for SFS system with scoured foundations

The considered SFS model consists of a superstructure with lumped mass  $m_s$ , lateral stiffness  $k_s$ , height  $h_s$ , and a foundation with mass  $m_f$ , height  $2h_f$ , width  $2b_f$  and mass moment of Inertia  $I_f$  (Figure 6). The foundation rests on a soil domain with shear modulus  $G$ , mass density  $\rho$  and Poisson's ratio  $\nu$ , while the soil-foundation compliance is expressed through the already calculated impedance functions (see Section 2.4.). The system has three degrees of freedom, namely the foundation translation ( $u_f$ ) and rotation ( $\theta_f$ ), and the relative displacement  $u_s$  of mass  $m_s$  with respect to the base.

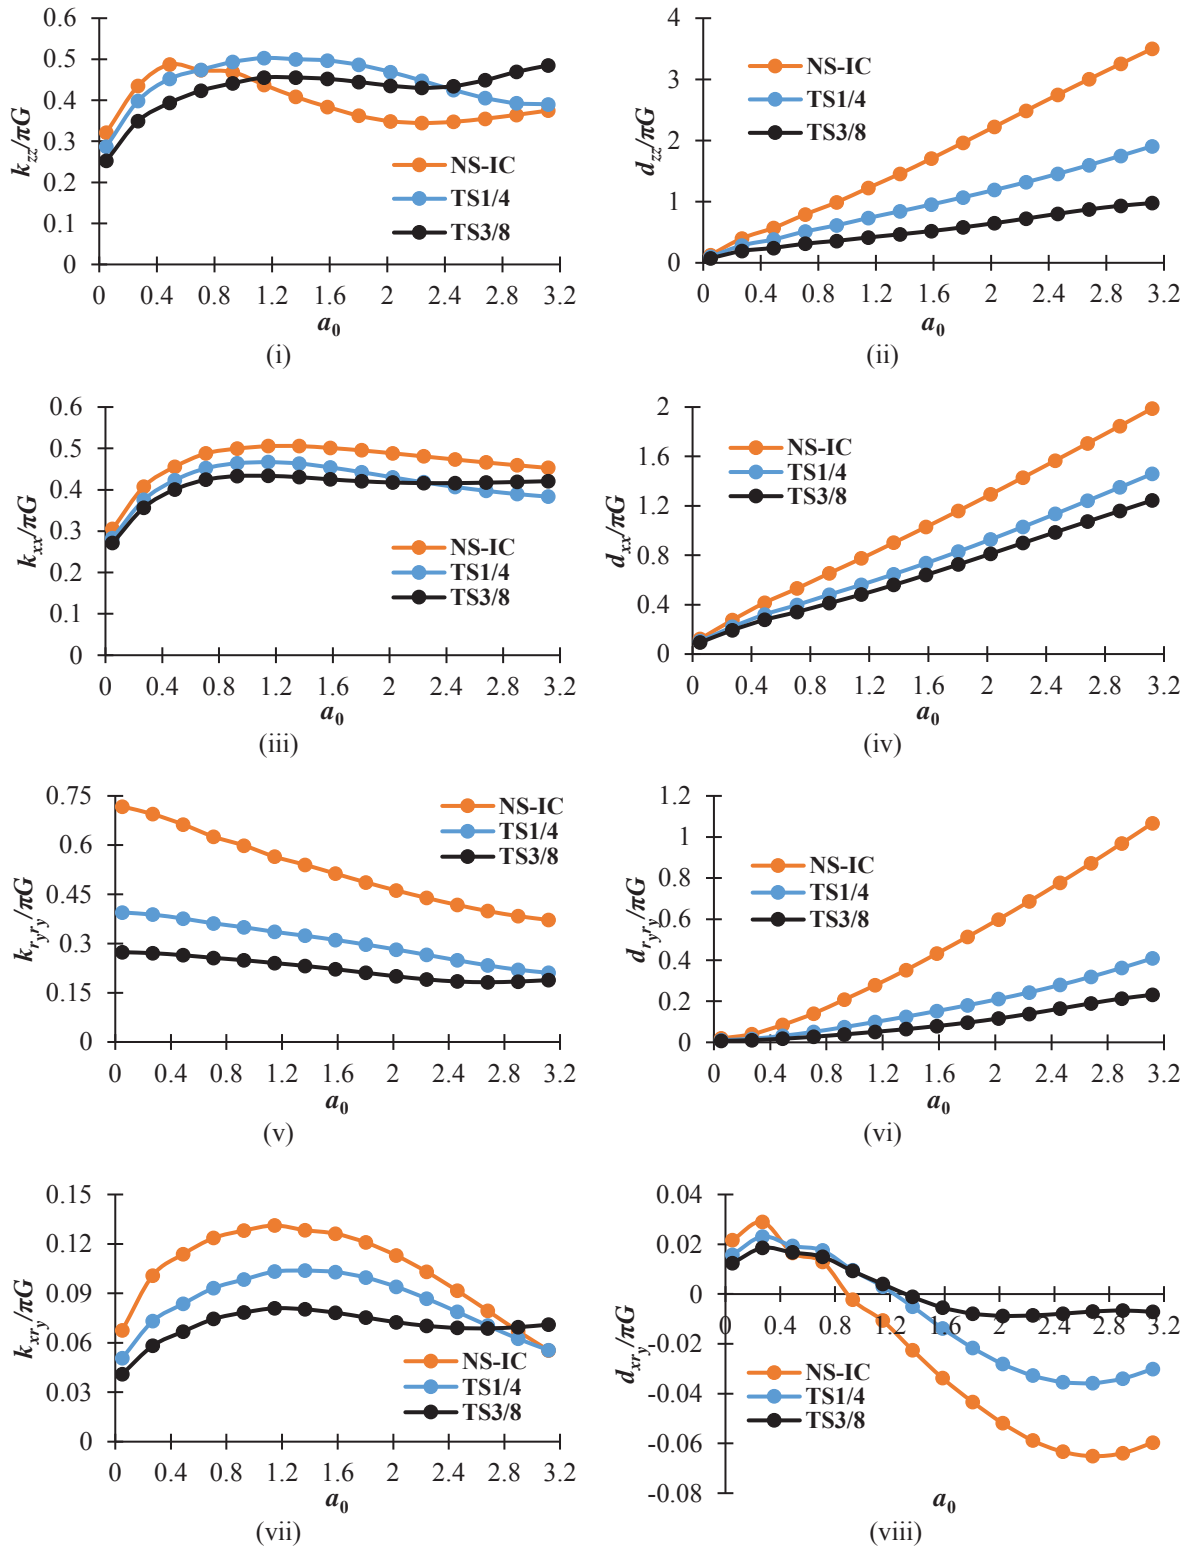

Figure 5: Comparisons of the calculated impedance functions for different scour scenarios (i)  $k_{zz}$ , (ii)  $c_{zz}$ , (iii)  $k_{xx}$ , (iv)  $c_{xx}$ , (v)  $k_{yy}$ , (vi)  $c_{yy}$ , (vii)  $k_{xy}$ , (viii)  $c_{xy}$

Figure 6: Model of the SFS system (coupling terms are not illustrated).

The equation of motion of the free vibrations for the above described SFS system can be expressed in the frequency domain in a vector form as:

$$-\omega^2 \mathbf{M} \bar{\mathbf{U}} + i\omega \mathbf{C}(\omega) \bar{\mathbf{U}} + \mathbf{K}(\omega) \bar{\mathbf{U}} = 0 \quad (4)$$

where  $\bar{\mathbf{U}}$  denotes the Fourier transform of the vector collecting the system translational and rotational degrees of freedom, while  $\mathbf{M}$ ,  $\mathbf{C}$  and  $\mathbf{K}$  are the mass, damping and stiffness matrices of the system, respectively. Vector and matrices appearing in Eq. 4 are expressed as follows [30]:

$$\mathbf{U} = \begin{bmatrix} u_f & \theta_f & u_s \end{bmatrix}^T \quad (5)$$

$$\mathbf{M} = \begin{bmatrix} m_f + m_s & m_f h_f + m_s h & m_s \\ m_f h_f + m_s h & I_f + m_f h_f^2 + m_s h^2 & m_s h \\ m_s & m_s h & m_s \end{bmatrix} \quad (6)$$

$$\mathbf{C}(\omega) = \begin{bmatrix} c_{xx}(\omega) & b_f c_{xr_y}(\omega) & 0 \\ b_f c_{xr_y}(\omega) & b_f^2 c_{r_yr_y}(\omega) & 0 \\ 0 & 0 & c_s \end{bmatrix} \quad (7)$$

$$\mathbf{K}(\omega) = \begin{bmatrix} k_{xx}(\omega) & b_f k_{xr_y}(\omega) & 0 \\ b_f k_{xr_y}(\omega) & b_f^2 k_{r_yr_y}(\omega) & 0 \\ 0 & 0 & k_s \end{bmatrix} \quad (8)$$

For the sake of simplicity, the damping of the system is neglected by assuming the imaginary parts of the impedance functions to be zero. Therefore, the fundamental vibration frequency of the system can be found by solving the eigenvalue problem of Eq. 4, which can be rewritten as follows:

$$\begin{aligned} -\omega^2 m_s (\bar{u}_f + h \bar{\theta}_f + \bar{u}_s) - \omega^2 m_f (\bar{u}_f + h_f \bar{\theta}_f) + \bar{k}_{xx} \bar{u}_f + b_f \bar{k}_{xr_y} \bar{\theta}_f &= 0 \\ -\omega^2 m_s h (\bar{u}_f + h \bar{\theta}_f + \bar{u}_s) - \omega^2 I_f \bar{\theta}_f - \omega^2 m_f h_f (\bar{u}_f + h_f \bar{\theta}_f) + b_f \bar{k}_{xr_y} \bar{u}_f + b_f^2 \bar{k}_{r_yr_y} \bar{\theta}_f &= 0 \\ -\omega^2 m_s (\bar{u}_f + h \bar{\theta}_f + \bar{u}_s) + \bar{k}_s \bar{u}_s &= 0 \end{aligned} \quad (9)$$

where  $\bar{k}$  contains both the real and imaginary part of the impedances ( $\bar{k}_{ij}=k_{ij}+i\omega c_{ij}$ ).

Eq. 9i and Eq. 9iii can be written as:

$$\bar{\theta}_f = -\frac{\omega^2 m_s (\bar{u}_f + \bar{u}_s) - \bar{k}_{xx} \bar{u}_f + \omega^2 m_f \bar{u}_f}{-b_f \bar{k}_{xry} + h\omega^2 m_s + h_f \omega^2 m_f} \quad (10)$$

$$\bar{\theta}_f = \frac{\bar{k}_s \bar{u}_s - \omega^2 m_s (\bar{u}_f + \bar{u}_s)}{h\omega^2 m_s} \quad (11)$$

Equating Eq. 10 and Eq. 11 one obtains:

$$\bar{u}_f = \frac{\frac{\bar{k}_s \bar{u}_s - \omega^2 m_s \bar{u}_s}{h\omega^2 m_s} + \frac{\omega^2 m_s \bar{u}_s}{-b_f \bar{k}_{xry} + h\omega^2 m_s + h_f \omega^2 m_f}}{\frac{1}{h} - \frac{\omega^2 m_f - \bar{k}_{xx} + \omega^2 m_s}{-b_f \bar{k}_{xry} + h\omega^2 m_s + h_f \omega^2 m_f}} \quad (12)$$

Entering Eq. 12 into Eq. 11 yields:

$$\bar{\theta}_f = \frac{\bar{k}_s \bar{u}_s - \omega^2 m_s \left( \bar{u}_s + \frac{\frac{\bar{k}_s \bar{u}_s - \omega^2 m_s \bar{u}_s}{h\omega^2 m_s} + \frac{\omega^2 m_s \bar{u}_s}{-b_f \bar{k}_{xry} + h\omega^2 m_s + h_f \omega^2 m_f}}{\frac{1}{h} - \frac{\omega^2 m_f - \bar{k}_{xx} + \omega^2 m_s}{-b_f \bar{k}_{xry} + h\omega^2 m_s + h_f \omega^2 m_f}} \right)}{h\omega^2 m_s} \quad (13)$$

Entering Eq. 12 and Eq. 13 into Eq. 9ii finally gives the following homogeneous equation:

$$(\alpha + \beta + \gamma) \bar{u}_s = 0 \quad (14)$$

where:

$$\alpha = (-b_f \bar{k}_{xry} + h_f m_f \omega^2 + h m_s \omega^2) \delta \quad (15)$$

$$\beta = \left( b_f^2 \bar{k}_{r_y r_y} - h^2 m_s \omega^2 - h_f^2 m_f \omega^2 - I_f \omega^2 \right) \frac{\bar{k}_s - m_s \omega^2 (1 - \delta)}{h m_s \omega^2} \quad (16)$$

$$\gamma = -h m_s \omega^2 \quad (17)$$

$$\delta = \frac{\frac{\bar{k}_s - m_s \omega^2}{h m_s \omega^2} - \frac{m_s \omega^2}{b_f \bar{k}_{xry} - h m_s \omega^2 - h_f m_f \omega^2}}{\frac{\bar{k}_{xx} - m_f \omega^2 - m_s \omega^2}{b_f \bar{k}_{xry} - h m_s \omega^2 - h_f m_f \omega^2} - \frac{1}{h}} \quad (18)$$

The solution of the eigenvalue problem described by Eq. 14 is elaborate, since impedances  $k_{xx}$ ,  $k_{xry}$ ,  $k_{ryry}$  are functions of the excitation frequency and depend on  $G$ ,  $V_s$ ,  $b_f$ . In literature there are various approaches for solving this eigenvalue problem, and thus to evaluate the system resonance frequency  $\tilde{\omega}$  (see e.g. [31, 32]). In this paper, the resonance frequency is derived by solving repeatedly Eq. 14. In more detail, each time Eq. 14 is solved for the values

of the impedance function  $k_{xx}$ ,  $k_{xy}$ ,  $k_{ry}$ , which correspond to a specific excitation of frequency  $\omega$ . The one for which  $\omega = \tilde{\omega}$  is the solution of the problem.

The above described procedure is implemented considering a SFS whose properties are consistent with the the EuroProteas' prototype [33]. The superstructure is characterised by a height  $h_s = 4.2$  m, lateral stiffness  $k_s = 2672.16$  kN/m<sup>2</sup>, mass  $m_s = 6.11$  ton/m and it is based on a strip foundation with width  $2b_f = 3$  m, thickness  $2h_f = 0.4$  m mass  $m_f = 3.05$  ton/m and moment of inertia  $I_f = 2.33$  ton·m<sup>2</sup>/m. The soil beneath the foundation is described by a shear modulus  $G = 31.47$  MPa and shear wave velocity  $V_s = 130$  m/s. Figure 7 illustrates the values of the fundamental frequency of the system for different levels of scour, calculated using the impedance functions of Section 2. It can be observed that the natural frequency of the system decreases linearly for increasing widths and thus depths of scour. The reduction of frequency is of the order of 30% when the width of the scour hole beneath the foundation is about 1/3 of the foundation total width.

Figure 7: Fundamental vibration frequency of the SFS system for four different scour scenarios.

## 4 CONCLUSIONS

The impact of scour on the dynamic behaviour of bridges has been studied in this paper, by considering a soil-foundation-structure (SFS) system representative of a bridge pier. This SFS system consists of a single degree of freedom superstructure on a rigid strip foundation resting on an elastic soil domain. Initially, a massless rigid strip foundation is simulated in Abaqus to calculate its impedance functions in the case of no scour. Subsequently, the model is validated by comparing the derived impedance functions with the analytical estimates obtained by Hryniewicz [23]. Consequently, the model is used for a numerical investigation of the effects of scour on impedances, considering two scour scenarios with increasing width and depth. Based on the results of this study, the following conclusions can be drawn:

- In general, the foundation impedances are affected differently by scour, depending on the scour hole size and excitation frequency.
- The values of both the real and imaginary parts of the impedance functions decrease for increasing scour width (and thus depth) at low frequencies. On the other hand, for high frequencies a clear general trend cannot be identified, since scour affects the various components differently.

In the second part of the paper, the derived impedance functions are used to investigate the impact of scour on the fundamental vibration frequency of a SFS system, representative of a bridge pier. A linear decrease of the vibration frequency of the system is observed for increasing widths of scour. The variations of frequency are quite significant.

The results of this study can be used to develop inverse techniques for evaluating the extent of scour beneath bridge foundations based on an estimation of the changes of the vibration frequency of SFS systems. Future studies will consider a wider range of SFS systems and also three-dimensional models for the bridges and the soil domain.

## ACKNOWLEDGEMENTS

This work was supported by funding from the National Centre for Resilience (project title “Evaluating the benefit of structural health monitoring for improving bridge resilience against scour”) and by the Scottish Road Research Board (project title “Decision Support System based on “adaptive” Flood Level Markers”).

### Abstract

*The problem of kinematic bending moments imposed at the head of a single pile during the passage of seismic waves is explored under large shear strains in the surrounding soil. To this end, non-linear soil response at free-field conditions is derived numerically by a freely-available 1D code and then utilized to calibrate the constitutive law of soil introduced in a rigorous 3D Finite-Difference (FD) model of the soil-pile system employed to obtain pile's head bending moments. The pile is considered embedded to a normally-consolidated clay and seven earthquake records with different amplitude and frequency content are imposed as input motions at the base of the soil layer, thus allowing the investigation of pile kinematic bending with increasing levels of shear strains in the soil, exceeding the limit of equivalent-linear soil behavior. The performance of a simple analytical expression for predicting the kinematic bending moment at the pile-head is compared to the rigorous FD solution. It is concluded that this simple solution is still applicable, with slight modifications, for high shear strains related to non-linear soil behavior close to shear failure, provided that the proper mobilized soil properties from 1D soil response analysis are introduced.*

## 1 INTRODUCTION

Piles in earthquake-prone areas are traditionally designed to withstand inertial forces and moments coming from the oscillation of the superstructure. However, during the passage of seismic waves in the soil, an additional loading source is generated due kinematic interaction between pile and soil, which forces the pile to deform along its whole length, thus imposing additional bending on the pile. In some cases, this kinematic bending induced at the pile-head or at deeper elevations close to interfaces of soil layers with sharp stiffness contrast may be larger than pile bending due to inertial forces. Empirical evidence on this critical aspect of pile bending has been provided by post-earthquake observations in non-liquefiable soils [1–3]. The above field surveys recognized pile failures at depths where inertial forces from the superstructure are negligible. Thus, a reliable prediction of pile-head kinematic bending should follow a proper modelling of soil behavior at free-field conditions to estimate the deformation demand which the soil tries to impose on the pile.

To this end, the Equivalent Linear (EL) method is widely employed to derive free-field soil response when shear strains in the soil do not exceed a threshold value being around 0.2% [4]. In this case, soil response is far from failure and the EL approximation allows a reliable prediction of soil response by considering soil stiffness degradation and hysteretic damping increase with increasing strain. Under these conditions and upon considering for example a continuously inhomogeneous soil, a simplified analytical expression that is available in the literature [5] may be employed to assess kinematic pile-head bending moments by utilizing the mobilized stiffness of the soil which is compatible to the induced shear strains in free-field conditions.

On the other hand, under larger shear strains that may be generated when a soft soil is subjected to strong earthquake shaking, the assumption of soil response being controlled only by soil stiffness is no longer appropriate, since the shear strength of the soil plays a dominant role and, therefore, soil response cannot be captured by considering its stiffness degradation alone [6]. In this case, free-field ground response may be derived by a pertinent 1D analysis with a freely-available software like DEEPSOIL [7] once soil stiffness and strength properties are known. On the contrary, the prediction of pile kinematic bending under large shear strains in the soil seems to be possible only by numerical analyses of complex soil-pile models with advanced constitutive laws at least for the soil.

Upon considering that such type of analyses are excessively demanding for pile design practice, this paper explores the applicability of the abovementioned analytical formula by properly adapting its input parameters in the presence of shear strains close to soil failure. For this reason, a series of Finite-Difference (FD) analyses are performed by employing experimentally validated constitutive models for the case of a normally-consolidated clay. Rigorous analyses results in terms of kinematic pile-head bending are compared with the predictions of a proposed analytical expression including frequency effects.

## 2 SOIL-PILE SYSTEM UNDER STUDY

The system under investigation refers to a single fixed-head pile embedded in a 30m thick soil layer resting on a rigid base (Figure 1). The pile is a linear elastic cylindrical solid beam of diameter  $d = 1$  m, length  $L = 20$  m, Poisson's ratio  $\nu_p = 0.15$ , unit weight  $\rho_p = 24$  kN/m<sup>3</sup> and elastic modulus  $E_p = 25$  GPa. A soft normally-consolidated clay layer is considered the low-strain stiffness and strength properties of which are described in the ensuing.

Figure 1: Single elastic fixed-head pile in a normally-consolidated (NC) clay soil.

## 2.1 Normally-consolidated (NC) Clay properties

A fine-grained, fully saturated normally-consolidated (NC) clay having a unit weight  $\gamma_{\text{sat}} = 17.9 \text{ kN/m}^3$  and a plasticity index  $I_p = 40\%$  is considered. The ratio  $s_u / \sigma'_{v0}$  of the undrained shear strength ( $s_u$ ) over the vertical effective geostatic stress for a NC clay can be derived by [8]:

$$\frac{s_u}{\sigma'_{v0}} = 0.11 + 0.0037 I_p \quad (1)$$

with  $I_p$  expressed in percentage. For  $I_p = 40\%$  the above expression yields:

$$s_u (\text{kPa}) = 2.1z \quad (2)$$

where  $z$  is the depth from the ground surface. Upon considering that the low-strain shear modulus  $G_0$  is proportional to depth through a multiplier of the associated shear strength profile (i.e.  $G_0 = 800s_u$ ) the following distribution of  $G_0$  with depth is obtained:

$$G_0 (\text{MPa}) = 1.7z \quad (3)$$

which corresponds to a shear wave propagation velocity profile in the form:

$$V_{s0} = 30z^{0.5} \quad (4)$$

and a  $V_{s,30}$  value at 100 m/s, referring to soil type D according to EC8. The above expression was also adopted by Travasarou and Gazetas [9] to describe the  $V_{s0}$  profile of a particularly soft normally consolidated clay in a real site. The above low-strain stiffness and the strength profiles are plotted in Figure 1.

## 2.2 Input motions

A set of seven earthquake recordings selected from the PEER Strong Motion Database [10] were imposed at the base of the soil layer, in the form of vertically propagating SH waves, to investigate pile-head kinematic bending under seismic loading. The selected records were acquired from stations resting on soil type A or B of the USGS classification system. The 5%-damped acceleration response spectra of the selected motions normalized by the peak rock acceleration (PRA) are plotted in Figure 2. Three levels of increasing intensity of the input motion were examined by scaling the records to three levels of Peak Rock Acceleration (PRA) considered at 0.10g, 0.15g and 0.25g.

Figure 2: Normalized elastic response acceleration spectra of the selected input motions.

### 3 NUMERICAL ANALYSES

First, a one-dimensional free-field soil response analysis was performed with the DEEPSOIL code [7], by considering equivalent linear (EL) and non-linear (NL) soil behaviour. The Finite-Difference (FD) code FLAC3D [11] was then employed to perform non-linear time history analyses by implementing a rigorous 3D model of the soil-pile system with pertinent constitutive models to describe soil behaviour.

#### 3.1 DEEPSOIL non-linear soil model

The General Quadratic/Hyperbolic (GQ/H) model [12] was adopted to model the backbone curve of the shear stress-strain relationship for the non-linear (NL) analyses in time domain performed with DEEPSOIL. The GQ/H model allows the shear strength of the soil to be directly introduced as an input parameter, contrary to the Modified Kondner Zelasko (MKZ) model [13], which may overestimate the shear strength of the soil depending on the values of the curve-fitting parameters [14]. For the hysteretic soil behaviour during unloading and re-loading, the associated stress-strain loops were defined on the basis of the non-Masing Modulus Reduction and Damping with reduction Factor (MRDF) formulation proposed in Phillips and Hashash [15], to avoid damping overestimation at large shear strains when Masing rules are adopted [16].

#### 3.2 FLAC3D soil-pile model

Following a sensitivity analysis on critical modelling aspects such as model size, discretization scheme, pile and pile-soil interface, the final 3D FD soil – pile model (Figure 3) implemented in FLAC3D code, has a base, width, and height equal to 30m, 30m, and 31m, respectively. The one-meter-thick bottom layer models the elastic bedrock with a shear wave velocity at 800 m/s and the same unit weight like the soil layers above. The grid-element size in the vertical direction (z-axis) was selected according to the indications provided in Kuhlemeyer and Lysmer [17]. The first 20 m were discretized with 80 layers of 0.25 m thickness each, while 20 layers of 0.50 m thickness each were adopted to discretize the soil profile between 20 and 30 m.

Figure 3: 3D Finite-Difference (FD) soil – pile model employed in FLAC3D code.

The same discretization was adopted in the DEEPSOIL code, satisfying the criterion of a frequency  $f_{\max,i}$  ( $= V_{s0,i} / 4H_i$ ), that a layer of thickness  $H_i$  and shear wave velocity  $V_{s0,i}$  can propagate, above 25 Hz [7]. A linear elastic behavior of the pile material and a bonded connection between soil and pile elements were assumed. The latter was based on the fact that soil-pile contact stresses under kinematic loading are negligible compared to those induced by forces or moments applied at the pile-head [18].

Nonlinear soil response in dynamic analyses was accounted for by means of the UCSDCLAY model [19]. The UCSDCLAY model is a pressure-independent 3D elasto-plastic material model, which enables reproducing nonlinear hysteric shear behavior, and it allows the shear strength of the soil to be introduced as a direct input. Rayleigh damping, which is commonly applied to take into account small strain (viscous) damping or to remove high frequency noise, was found to be unnecessary.

### 3.3 UCSDClay model calibration

A recursive calibration procedure was followed to obtain similar non-linear behavior between the GQ/H and USCDClay models. In this regard, the following steps were performed: (Figure 4): (i) first, the GQ/H model was calibrated by the Vucetic and Dobry [20] curves for  $I_p = 40\%$  (noted in Figure 4 as “DS fit.1”), (ii) the fitted DEEPSOIL curves were employed to calibrate the USCDClay model introduced in FLAC3D and (iii) the fitted FLAC3D-based curves were employed to calibrate again the GQ/H model (noted in Figure 4 as “DS fit.2”). In this manner, it was possible to derive comparable  $\tau - \gamma$  backbone curves between the two models (Figure 4c) at the expense of higher hysteretic damping at large strains with respect to the experimental data (Figure 4b).

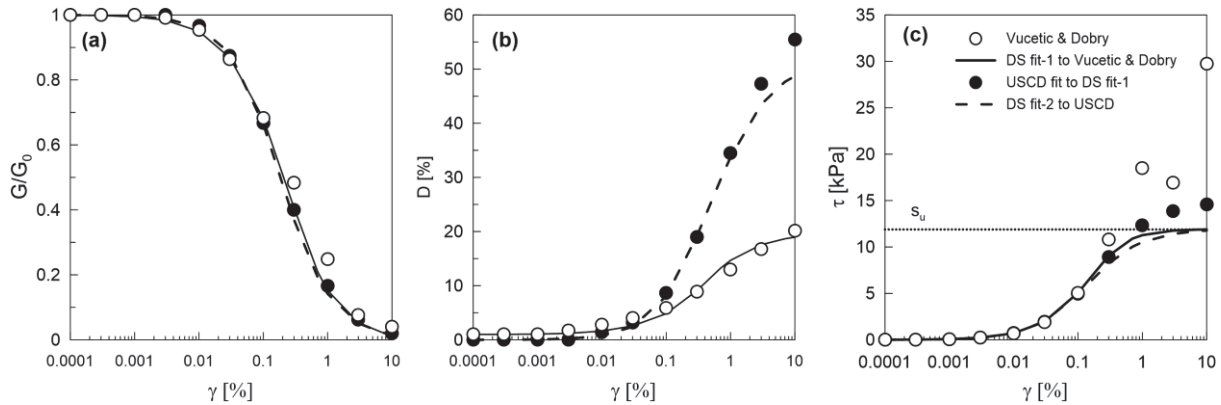

Figure 4: Calibration of DEEPSOIL and FLAC3D soil models for the NC Clay case based on Vucetic and Dobry [20]  $G/G_0 - \gamma - D(\%)$  curves for  $I_p = 40\%$  regarding: (a) Stiffness degradation, (b) Hysteretic damping increase and (c) Shear stress-strain backbone curve at the depth of 4.375m (the implied shear strength derived in DEEPSOIL is also mentioned).

#### 4 SOIL RESPONSE AT FREE-FIELD CONDITIONS

Non-linear analyses results of the free-field ground response derived with DEEPSOIL code under the prescribed input motions is shown in Figure 5, in terms of peak ground acceleration (Figure 5a), maximum shear strain (Figure 5b) and maximum shear stress (Figure 5c) profiles, referring to average values between those computed separately for each one of the seven base excitations. An effective shear strain profile was then computed as 0.65 times the maximum strain developed at any depth and was then employed to obtain the corresponding mobilized shear modulus and damping profiles based on the calibrated  $G/G_0 - \gamma - D(\%)$  curves. In this manner, a single mobilized stiffness and damping profile was derived for each one of the seven input motions. An average mobilized  $G$  profile obtained by averaging these seven profiles is shown in Figure 5d. All the results shown in Figure 5 correspond to the maximum PRA at 0.25g. The same analyses results obtained with DEEPSOIL by implementing this time the Equivalent Linear (LE) approximation to model soil behavior are also plotted in Figure 5. In this case, a frequency independent expression [i.e.  $G^* = G(1+2iD)$ ] was adopted for the complex formulation of the shear modulus while the effective shear strain ratio was set at 0.65. The degradation of the shear modulus and the increase of the hysteretic damping of the soil with increasing shear strain were modeled by implementing the  $G/G_0 - \gamma - D(\%)$  curves proposed in Vucetic and Dobry [20] for the plasticity index under consideration ( $I_p = 40\%$ ). It is noted that for the first 1.5 m of the soft NC clay profile, the low-strain shear modulus ( $G_0$ ) and the undrained shear strength ( $s_u$ ) were considered constant at 2.55 MPa and 6.2 kPa, respectively, due to a numerical issue observed in DEEPSOIL when very low values of the above parameters are introduced. Below 1.5m, the  $s_u$  and the  $G_0$  profiles follow the linear variation with depth described by Equations 2 and 3, respectively.

It is observed that under the EL assumption, a sudden increase of the peak ground acceleration is observed close to the ground surface, being in qualitative agreement with analytical elasto-dynamic investigations reported in Rovithis et al. [21] for a similar shear wave velocity profile. On the contrary, when the non-linear behavior of soil is modeled by the rigorous GQ/H model, ground acceleration is de-amplified as it propagates through the soil due to the low shear strength of the soft clay, which limits the transmission of shear stresses. Such a behavior has also been reported in experimental studies of the seismic behavior of soft clays [22]. This indicates that the EL approximation is not able to capture the complex soil behavior, which is also reflected in the  $\tau$ - $\gamma$  loops derived at two depths close to the ground surface (Figure 6) for PRA = 0.25g. The strong non-linear behavior of the soil generates large inelastic

strains on the order of 1%, while the developed shear stresses are bounded by the low shear strength  $s_u$  of the soft clay. Apparently, the above soil response cannot be reproduced by the linear elastic  $\tau$ - $\gamma$  relationship under the EL assumption (Figure 6). This does not mean absence of energy dissipation through the hysteretic behavior of the soil, as the latter is taken into account through the complex shear modulus during each iteration of an EL analysis.

The corresponding average profiles of free-field ground response obtained with FLAC3D are also plotted in Figure 5. The agreement between DEEPSOIL NL and FLAC3D analysis indicates that critical trends of ground response may be reproduced in a similar manner, which provides confidence that the adopted model in FLAC3D is able to reproduce highly non-linear ground response and, therefore, kinematic soil-pile interaction over a wide range of shear strains.

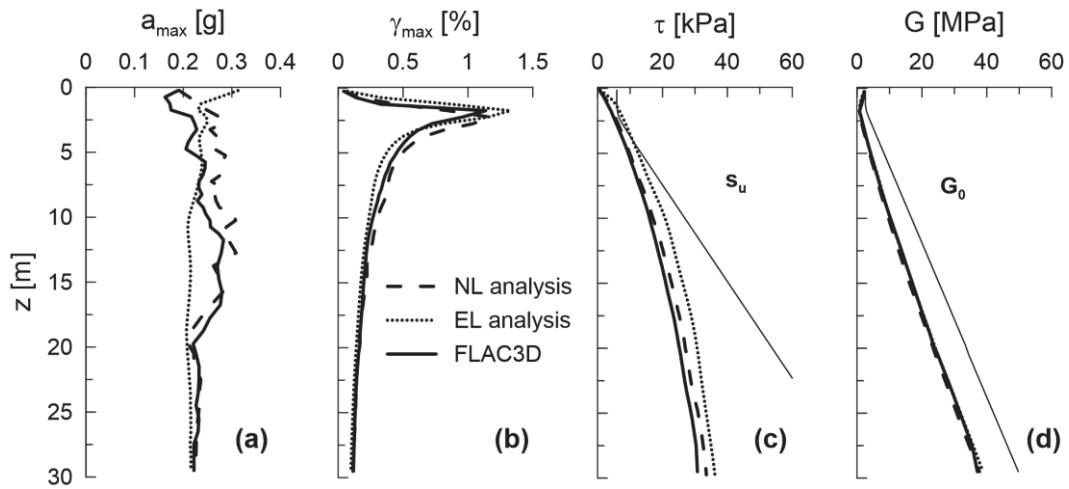

Figure 5: Comparison of free-field ground response analysis results between DEEPSOIL (EL and NL analysis) and FLAC3D for the NC clay profile in terms of: (a) PGA profile (b) average maximum shear strain profile (c) average shear stress and (d) mobilized shear modulus  $G$  with depth. All plots refer to  $PRA = 0.25g$ .

Figure 6: Comparison of EL and NL soil response analysis with DEEPSOIL for the NC clay profile in terms of  $\tau$  -  $\gamma$  loops at the depth of: (a) 2.625 m and (b) 5.125 m. All plots refer to  $PRA = 0.25g$ .

## 5 PILE-HEAD KINEMATIC BENDING

In the general case of an inhomogeneous soil profile with shear stiffness varying continuously with depth according to the law:

$$G_s(z) = G_{sd} \left[ a + (1-a) \frac{z}{d} \right]^n \quad (5)$$

where  $G_s(z)$  is the depth-varying soil shear modulus,  $G_{sd}$  is the shear modulus at the depth of one pile diameter (i.e., at  $z = d$ ) and  $a, n$  are dimensionless factors controlling the stiffness profile, the active length ( $L_a$ ) of the pile may be calculated by the expression [5, 23, 24]:

$$L_a = \frac{d}{1-a} \left\{ \left[ a^{\frac{n+4}{4}} + \frac{5}{16} (n+4) (1-a) \left( \frac{\pi E_p}{2 E_{sd}} \right)^{\frac{1}{4}} \right]^{\frac{4}{n+4}} - a \right\} \quad (6)$$

where  $E_{sd}$  is the Young's modulus of elasticity of the soil at one pile diameter depth.

### 5.1 Constant ground acceleration

Upon considering that there is an effective portion of the soil controlling pile-head bending, which is proportional to a characteristic wavelength of the soil-pile system, Di Laora and Rovithis [5] introduced the notion of an effective soil curvature  $[(1/R)_{s,eff}]$  as the ratio of the shear strain  $\gamma_s(z_{eff})$  at an effective depth  $z_{eff}$  over  $z_{eff}$  [i.e.  $(1/R)_{s,eff} = \gamma_s(z_{eff}) / z_{eff}$ ] to derive a simple analytical expression for the kinematic bending moment at the head of a pile in a continuously inhomogeneous soil, such as that described by Equation 5, and proved that under constant ground acceleration,  $a_s$ , the ratio of the pile-head curvature  $(1/R)_p$  over  $(1/R)_{s,eff}$  for long piles is equal to 1, which allows calculation of pile-head kinematic bending by the formula:

$$M_{kin} = E_p I_p (1/R)_p = E_p I_p (1/R)_{s,eff} = E_p I_p \frac{\gamma_s(z_{eff})}{z_{eff}} \quad (7)$$

where the depth  $z_{eff}$  is considered as one half of the pile's active length  $L_a$ :

$$z_{eff} = \frac{L_a}{2} \quad (8)$$

The equilibrium of a 1D soil column with constant mass density  $\rho_s$  and variable shear modulus  $G(z)$  with depth yields that in static conditions  $\gamma(z_{eff})$  may be expressed as:

$$\gamma_s(z_{eff}) = \frac{a_s \rho_s z_{eff}}{G_s(z_{eff})} \quad (9)$$

where  $G(z_{eff})$  is the mobilized shear modulus of the soil at  $z_{eff}$ . Thus, Equation 7 may be re-written as:

$$M_{kin} = E_p I_p \frac{a_s \rho_s}{G_s(z_{eff})} \quad (10)$$

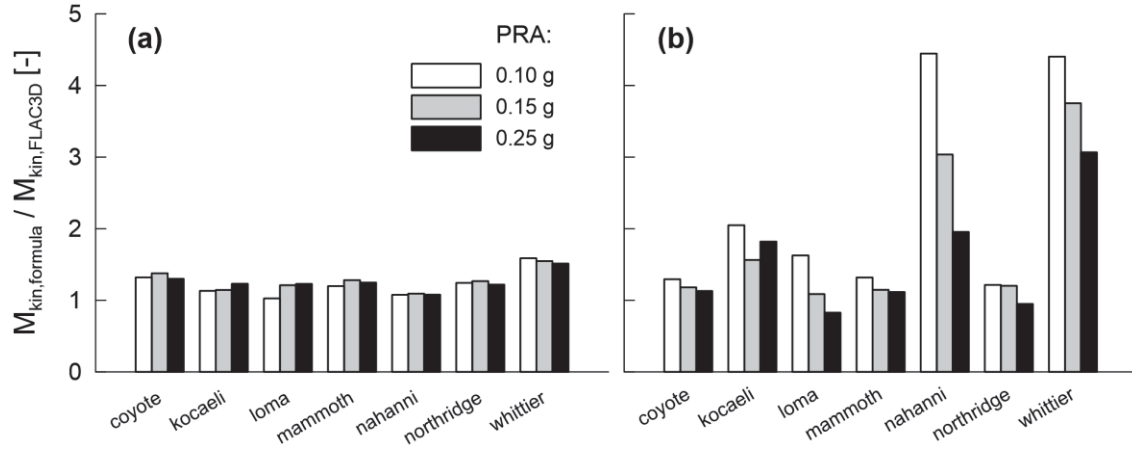

Figure 7: Ratios of kinematic pile-head bending moment between 3D FD analyses (FLAC3D) and the predictions of (a) Equation 7 and (b) Equation 10.

In order to apply the above formulae, one has fit the mobilized shear modulus profile derived from 1D ground response analysis, to the formula of  $G_s(z)$  in Equation 5 in order to obtain the parameters  $G_{sd}$ ,  $a$  and  $n$  and then calculate  $L_a$  and  $z_{eff}$  from Equations 6 and 8, respectively. As the above parameters are interrelated, an iterative procedure may be followed by considering the value of  $L_a = 10d$  as a starting point and employing a least square linear (i.e.  $n = 1$ ) fit. A single iteration leads to quite accurate results.

The performance of Equations 7 and 10 is compared to the rigorous 3D Finite-Difference model response in Figure 7, in the form of  $(M_{kin,formula} / M_{kin,FLAC3D})$  ratio for all the examined input motions scaled to 0.10g, 0.15g and 0.25g. Each group of bars refers to a different base excitation noted in the abscissa of the plots. To this end, the maximum shear strain  $\gamma_{max,s}(z_{eff})$  at  $z_{eff}$  was introduced in Equation 7, while the peak ground acceleration at soil surface was employed to derive  $M_{kin,formula}$  in Equation 10. Both of these parameters were obtained by the FLAC3D analyses for the purpose of this comparison.

It is observed that for the particularly soft NC Clay under consideration, where the maximum shear strain at  $z_{eff}$  attains considerably large values up to 0.8 - 1 % (Figure 5b), the kinematic pile-head bending predicted by Equation 7 is much closer to the rigorous FD solution (Figure 7a), denoting that the maximum shear strain at  $z_{eff}$  is a better indicator of the developed pile-head bending compared to the peak ground acceleration at surface (Figure 7b), when soil behavior is close to failure (Figure 5c). However, despite its better performance, Equation 7 may still be quite conservative for certain base excitations, like in the case of the Whittier base motion where an overestimation of 50% is attained.

## 5.2 Frequency effects: Proposed analytical expression

The above over-prediction of kinematic bending is explainable, though, as it follows the original conservative assumption of constant ground acceleration to derive Equation 7, implying low-frequency excitations. This is valid if the frequency content of the time variant parameter  $\gamma_s(z_{eff})$  controlling the kinematic demand is low enough to be considered as almost statically applied. Otherwise, the bending moment attains lower values as the shear strain (and the corresponding effective soil curvature) is a decreasing function of the excitation frequency regardless of the soil properties [5].

In this case, frequency effects in kinematic bending may be accounted for by implementing the expression of the dynamic  $(1/R)_{p,dyn}$  over the static  $(1/R)_{p,static}$  pile curvature ratio proposed in Di Laora and Rovithis [5]:

$$\frac{(1/R)_{p,dyn.}}{(1/R)_{p,static}} = \left[ 1 + 0.02 a_{eff,La}^3 \right]^{-1} \quad (11)$$

In the above expression,  $a_{eff,La}$  is a dimensionless frequency which controls the kinematic response of the pile in the dynamic regime [5, 24]:

$$a_{eff,La} = \frac{\omega L_a}{V_{s,av}} \quad (12)$$

where  $\omega$  is the cyclic frequency of the excitation,  $L_a$  is the active length of the pile (Equation 6) and  $V_{s,av}$  refers to an average shear wave velocity along  $z_{eff}$  given by:

$$V_{s,av} = V_{s,d} \frac{L_a (a-1)(n-2)}{4d} \left[ \left( a + (1-a) \frac{L_a}{d} \right)^{1-n/2} - a^{1-n/2} \right]^{-1} \quad (13)$$

where  $V_{sd}$  is the mobilized shear wave at one pile diameter depth which may be derived by the corresponding value of  $G_{sd}$  once the mobilized shear modulus profile is fitted to a linear function as mentioned above.

Obviously, Equation 11 is a continuous function of  $\omega$ . In order to obtain a single-valued prediction of the kinematic pile-head moments in the dynamic regime, a mean cyclic frequency  $\omega_{m,\gamma}$  is considered as an index of the frequency content of the shear strain time history at  $z_{eff}$ . Following the definition of the mean period ( $T_m$ ) of an acceleration time history introduced in Rathje et al. [25],  $\omega_{m,\gamma}$  may be computed from:

$$\omega_{m,\gamma} = 2\pi \frac{\sum_i c_{i,\gamma}^2}{\sum_i c_{i,\gamma}^2 \left( \frac{1}{f_i} \right)} \quad (14)$$

where  $C_{i,\gamma}$  refer to the Fourier amplitudes of the shear strain time history at  $z_{eff}$  and  $f_i$  are the discrete Fourier transform frequencies between 0.25 Hz and 20 Hz. In this manner, a mean dimensionless frequency  $a_{eff,m,La}$  of the shear strain demand at  $z_{eff}$  may be defined by introducing  $\omega_{m,\gamma}$  in Equation 12:

$$a_{eff,m,La} = \frac{\omega_{m,\gamma} L_a}{V_{s,av}} \quad (15)$$

Upon introducing  $a_{eff,m,La}$  in Equation 11, a single value of the  $(1/R)_{p,dyn} / (1/R)_{p,static}$  ratio may be computed for each base excitation according to the associated value of  $a_{eff,m,La}$ . Taking also into account that for long piles  $(1/R)_{p,static} = (1/R)_{s,eff}$ , the kinematic pile-head bending moment including frequency effects may be derived by the expression:

$$M_{kin} = E_p I_p \frac{\gamma_{max,s}(z_{eff})}{z_{eff}} \left[ 1 + 0.02 a_{eff,m,La}^3 \right]^{-1} \quad (16)$$

The performance of the above expression against the rigorous FD solution is compared in Figure 8. The improvement of the agreement between the two solutions with respect to that shown in Figure 7a cannot be overstated, denoting maximum deviations of less than 10%.

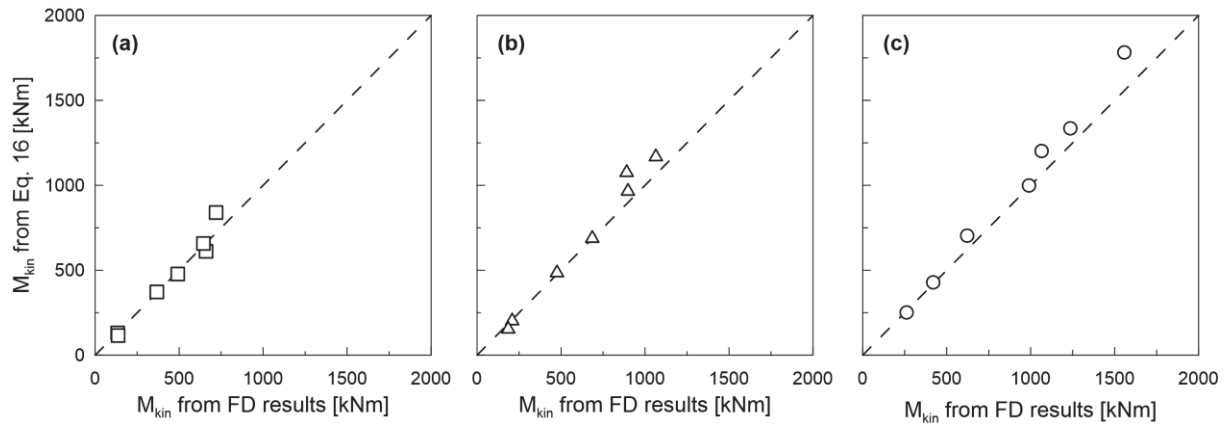

Figure 8: Comparison of kinematic pile-head bending moments between Equation 16 and FD results for PRA at (a) 0.10g (b) 0.15g and (c) 0.25g. Each point in the plots refers to a different input motion.

This suggests that the simple analytical formula in Equation 16 is applicable even in the highly nonlinear range of soil response close to failure, provided that the associated shear strain demand induced by the surrounding soil and the corresponding mobilized stiffness profile are introduced. It may thus be asserted that dynamic effects result in modifying solely soil deformations at free-field conditions while soil-pile kinematic interaction mechanism remains static. The latter was first discussed by Di Laora et al. [26] for homogeneous soils and confirmed further in Di Laora and Rovithis [5] for nonhomogeneous soils. The results of this study extend, therefore, the validity of the simple analytical solutions to the non-linear range of soil response, denoting that kinematic soil-pile interaction is controlled by the soil stiffness even if the response of the soil is controlled by its strength. The above finding generalizes earlier indications [27–30] of the controlling role of the mobilized soil stiffness on pile kinematic bending.

## 6 CONCLUSIONS

Kinematic pile-head bending moments were explored under increasing earthquake-induced shear strains in the soil, by means of a rigorous 3D Finite Difference model of the soil-pile system, taking into account both stiffness degradation and strength of the soil. The numerical results were compared to the predictions of a proposed simple formula properly adapted for the non-linear regime of soil response over an earlier publication of the Authors. The main conclusions can be summarized as follows:

- While in the linear and static regime Equations 7 and 10 return identical predictions of pile-head bending moments, in the non-linear regime the use of ground surface acceleration is no longer reliable and the maximum shear strain at an effective depth equal to one half of the pile's active length becomes the dominant soil response parameter controlling kinematic bending at the pile-head.
- The simplified formula in Equation 16 may be employed to derive kinematic pile-head bending in the non-linear dynamic range of soil response. In this regard, a 1D free-field non-linear soil response analysis, which properly considers both stiffness degradation and soil strength, should be performed to derive the necessary input parameters in the formula.
- A mean cyclic frequency was suggested (Equation 14) as a single index of the frequency content of the shear strain time history at one half of the pile's active length. Such an in-

terpretation of the frequency content of a shear strain time history has not been previously explored in the kinematic bending of piles.

- It was proven that dynamic and non-linear effects result in modifying solely soil deformations at free-field conditions, while soil-pile kinematic interaction mechanism remains static and linear. This shed lights to the actual nature of kinematic soil-pile interaction mechanism which may be considered as stiffness-controlled even if free-field soil response is strength-controlled.

### Abstract

*This paper presents experimental data from two series of centrifuge tests on pile foundations embedded in a kaolin clay under earthquake excitation. A single pile and two pile-group configurations were tested in the centrifuge at 50g. In the first test series (flight 1) the seismic response of the soil-pile system was monitored, allowing experimentally-driven insights on the kinematic interaction between soil and pile. In the second series of tests (flight 2), a superstructure mass was attached to each foundation model, allowing investigation of the seismic behaviour of the coupled soil-foundation-structure (SFS) system. Two earthquake excitations were analysed during each flight having similar frequency and amplitude characteristics. Results are presented in terms of soil response along a vertical array, pile-caps spectral acceleration and superstructure top-to-ground surface response ratio. Experimental data suggests that for soft soils such as those employed in this experimental campaign, piles may amplify the motion with respect to the one at ground surface, while the natural period of the SFS system may be largely increased compared to its fixed-base counterpart, indicating a strong effect of soil compliance.*

**Keywords:** centrifuge, kaolin clay, kinematic soil-pile interaction, coupled soil-structure system.

---

## 1 INTRODUCTION

Seismic analysis of structures supported on piles is conventionally performed by considering the structure fixed at its base and excited under the free-field motion at ground surface. The above considerations which are normally followed in design practice disregard the interaction between soil, piles and structures that takes place during earthquake shaking and may affect both the actual motion which is imposed at the base of the superstructure and the vibrational characteristics of the structure compared to its fixed-base counterpart, especially in the case of soft soils, where piles represent the most common design option. With reference to the modification of the free-field soil motion, the associated physical mechanism is related to the fact that, during the passage of seismic waves, piles, due to their flexural stiffness, are progressively unable to follow the wavy pattern of the soil with increasing frequency of excitation, which is referred to as kinematic soil-pile interaction [1-6]. Relevant empirical evidence has been documented by field measurements on instrumented pile-supported structures [7-9], indicating that piles may filter out the high frequency components of the free-field motion. Under certain conditions, such a filtering action may be particularly important. For example, Di Laora and de Sanctis [5] reported that in the case of large-diameter piles in soft soil, the seismic demand on a low-period structure may be up to 50% - 70% with respect to the demand imposed by the free-field motion. A holistic interpretation of the filtering action of piles has been very recently suggested in [10-11] by considering that piles average the non-uniform profile of displacement imposed by the surrounding soil along a fraction of the pile's active length.

On the other hand, the effect of soil compliance on the vibrational characteristics of a flexible-base structure, consisting of the elongation of the natural period and the modification of the energy dissipation mechanism with respect to the fixed-base case, has been well-established since the early 70s [12-19] and supported by relevant experimental data [20-23]. This phenomenon is due to soil hysteresis and radiation of seismic waves emanating from the foundation. Soil-foundation-structure interaction may have a detrimental or beneficial effect on the seismic loading imposed to the superstructure depending on the soil-foundation configuration and the characteristics of the earthquake excitation [24], especially, again, in the case of soft soils. The issue has been recognized by modern seismic codes that specify conditions where soil-pile-structure interaction should be taken into account.

Along these lines, a large centrifuge testing campaign was performed in the framework of the Transnational Access (TA) project COSMO funded by the SERA research program to explore the above aspects of soil-pile-structure interaction (SPSI) in a soft clay under earthquake loading. Part of the experimental data is presented in this paper, referring to the kinematic response of single piles and pile groups (i.e. in the absence of a supporting structure) and to the seismic response of the coupled soil-piles-structure (SPS) system, with the same pile layouts supporting a single degree of freedom (SDOF) structure. Experimental data are elaborated in terms of soil response along a vertical array, pile-cap spectral accelerations and superstructure top-to-ground surface response spectral ratio, following a detailed description of the centrifuge models preparation and testing procedure.

## 2 CENTRIFUGE MODELS AND TESTING PROCEDURE

The experiments were carried out at 50g in the Turner Beam centrifuge [25] at the Schofield Centre of the University of Cambridge. The foundation models reported herein consisted of a single pile (SP) and two 3x1 pile groups (PG1 and PG2) (Figure 1) installed in a kaolin clay. All piles were aluminum tubes of length  $L = 200$  mm, diameter  $d = 15$  mm and thickness  $t = 1$  mm, so that, in terms of flexural stiffness, they are equivalent to 0.75 m diame-

ter and high-strength concrete piles. In model scale dimensions, pile spacing in PG1 and PG2 configurations was considered at  $s = 64$  mm. The different heights of the pile groups' caps,  $D_1 = 20$  mm (mass = 90 g) and  $D_2 = 40$  mm (mass = 170 g), represented two different foundation embedment depths.

Figure 1: Model pile foundations and superstructures. Model (prototype) dimensions are in mm (m).

## 2.1 Centrifuge flights 1 and 2

Two centrifuge flights were successively performed (Table 1). In the first flight only the piled foundations embedded in the kaolin clay were tested to investigate kinematic soil-pile interaction under earthquake loading. Hollow Perspex caps were installed on model foundations to accommodate instruments and, with regard to the pile groups, to rigidly connect the piles' heads. Mass of the Perspex caps for the SP, PG1 and PG2 are 11 g, 90 g and 170 g, respectively, being thus negligible in comparison to the self-weight of the piles. Hence, the accelerations during flight 1 can be considered as the effect of kinematic interaction.

In the second flight, elevated aluminum caps were added to each foundation configuration to model a SDOF structure, thus allowing the experimental investigation of the seismic response of the coupled SPS system. It is noted that the fixed-base natural period of the SDOF was measured at 0.2 s in prototype scale.

Centrifuge flights	Foundation models	SDOF model on piles
flight 1	SP, PG1, PG2	No
flight 2	SP, PG1, PG2	Yes

Table 1: Model configurations included in centrifuge flights 1 and 2

## 2.2 Model preparation and soil properties

The model was prepared inside an Equivalent Shear Box (ESB) [26] (Schofield and Zeng 1992), in order to simulate field conditions accurately. It is a 645×230×400 mm rectangular box having alternate layers of rubber and aluminum rings (of width 75 mm), in order to reproduce the  $K_0$  conditions (zero lateral strains) and to match the shear deformation of the soil layer for a given earthquake. The bottom of ESB box was covered with a thin layer of filter

material and its inner surface was coated with silicone grease to minimize friction against the clay.

Laboratory grade Speswhite kaolin, whose mechanical behaviour has been extensively studied in Cambridge for many experimental campaigns [27-32] was used in the tests. Its properties are listed in Table 2. The kaolin clay powder was first mixed with de-aired water in 1:1.25 ratio under vacuum for two-three hours using the clay-mixer available in the Schofield Centre. The Clay slurry was then transferred into the ESB, once the instruments were fixed with utmost care. Under normal gravity (1g) conditions, the clay was allowed to consolidate on its self-weight for 24 hours and then the ESB box was placed under a computer controlled hydraulic press to consolidate under a vertical stress of 14.10 kPa. Simultaneously, the model was subjected to a suction of -90 kPa at the base. The purpose of a combination of vertical stress and suction-induced seepage consolidation is explained in detail in [32]. Once the clay was consolidated to stress level needed to achieve the desired undrained shear strength profile, the sample was unloaded and taken out from the consolidation chamber. At this stage, the model depth,  $H$ , and density,  $\rho_s$ , of the clay were 290 mm and 1.623 Mg/m<sup>3</sup>, respectively. Piles were then installed by gentle push into the clay layer at 1g.

Property	Value
Plastic limit, $PL$ [%]	30
Liquid limit, $LL$ [%]	63
Plasticity index, $I_P$ [%]	33
Specific gravity, $G_s$	2.60
Slope of critical state limit (CSL) in $q'$ - $p$ plane	0.90
Intercept of an unload-reload line, $\kappa$	0.039
Intercept of CSL at $p' = 1$ kPa, $\Gamma$	3.31
Slope of normal consolidation line, $\lambda$	0.22

Table 2: Properties of Speswhite kaolin clay (from Lau 2015 [29]).

### 2.3 Centrifuge models instrumentation

In order to capture the response of clay and pile foundations during the test, the model was equipped with (a) 11 Piezo-electric Accelerometers (PAs), to record the seismic accelerations developed in the clay; (b) 20 Micro-Electro-Mechanical System accelerometers (MEMSs), to measure both horizontal and vertical accelerations of pile foundations; (c) 6 Linearly Variable Differential Transformers (LVDTs), to monitor the settlement of clay, single piles and pile groups at different phases of testing; (d) 4 Pore Pressure Transducers (PPTs), to measure the pore pressure within the soil model; (e) an air hammer device (AHD), to determine soil stiffness. In order to fix the location of the instruments inside the box, five horizontal aluminum wires were settled in it and the clay slurry was transferred into the ESB box, once the instruments were fixed with utmost care. Figure 2 shows the schematic plan view and section of the model along with the exact locations of the instrumentation scheme.

Figure 2: Plan view and cross-section of the model showing instruments locations. Model dimensions are in mm.

## 2.4 Input motions

The model was swung up to 50g in the centrifuge, with gradual increments of 10g. Once the clay model attained equilibrium, it was subjected to a sequence of quasi-sinusoidal waves and real earthquakes (nine signals in total). Quasi-sinusoidal waves with different amplitude and predominant frequency and real earthquakes were applied throughout the servo-hydraulic shaker recently developed at the Schofield Centre [33]. Some results from the centrifuge experiments are discussed in the following sections, with reference to two real earthquakes, EQ1 and EQ2 (Figure 3) with similar peak acceleration close to 0.1g. The Fourier amplitude spectra and the response spectra of the two input motions are also shown in Figure 3. Soil response under a sine sweep input signal, with a maximum amplitude of 0.08g and frequency varying from 30 up to 150 Hz, was also elaborated as reported in the ensuing.

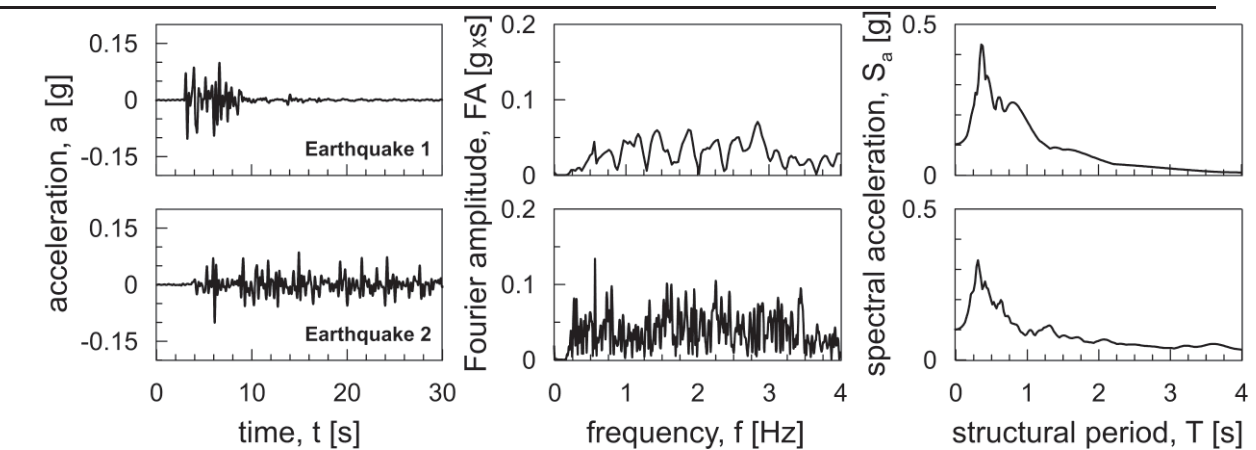

Figure 3: Earthquakes considered in the study (prototype scale).

### 3 SEISMIC BEHAVIOUR OF CLAY

Figures 4 (a) and (b) shows the maximum ground acceleration,  $a_{\max}$ , with depth for earthquakes 1 and 2, respectively. Accelerations in the soil are quite similar during flights 1 and 2 (Figure 4). This also suggests that soil stiffness and strength do not change significantly between the two flights and that superstructure has a minor effect on soil accelerations, even nearby the foundation.

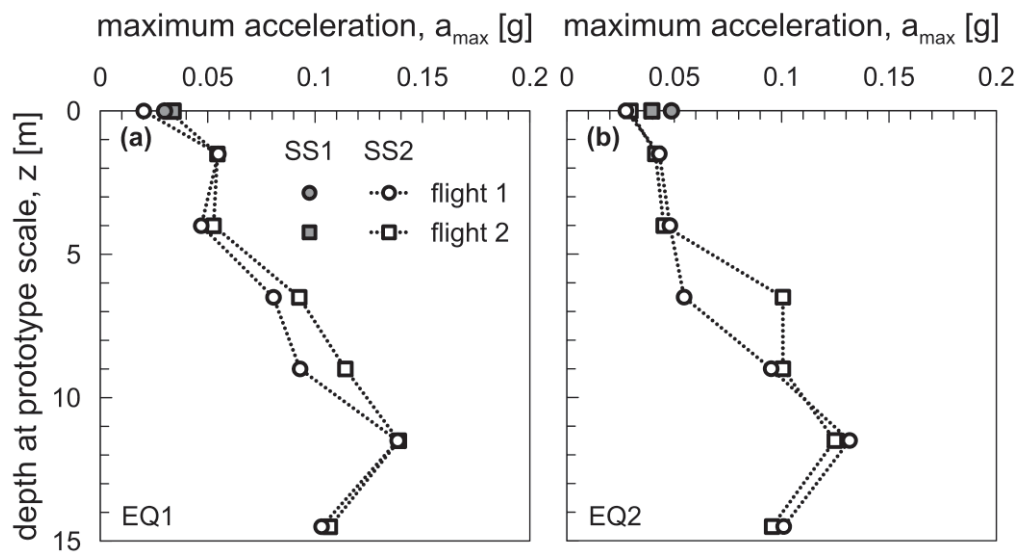

Figure 4: Maximum ground acceleration profile for (a) earthquake EQ1 and (b) earthquake EQ2. The location of SS1 and SS2 is shown in Figure 2.

For both earthquakes, an attenuation of maximum ground acceleration when approaching surface is observed. This suggests that soil may have reached close-to-failure shear stresses. Acceleration response spectra at different depths are plotted in Figure 5, showing that the high frequency components are filtered out by the layers either near the surface or nearby the base while low frequencies are still amplified.

The main intention behind the adoption of the sine-sweep excitation with a maximum amplitude of 0.08g and frequency varying from 30 up to 150 Hz was to determine the natural frequencies of soil layer and soil-foundations systems.

The measurements by the accelerometers on the surface and at the bottom of the model allow to estimate the soil layer amplification function (Figure 6).

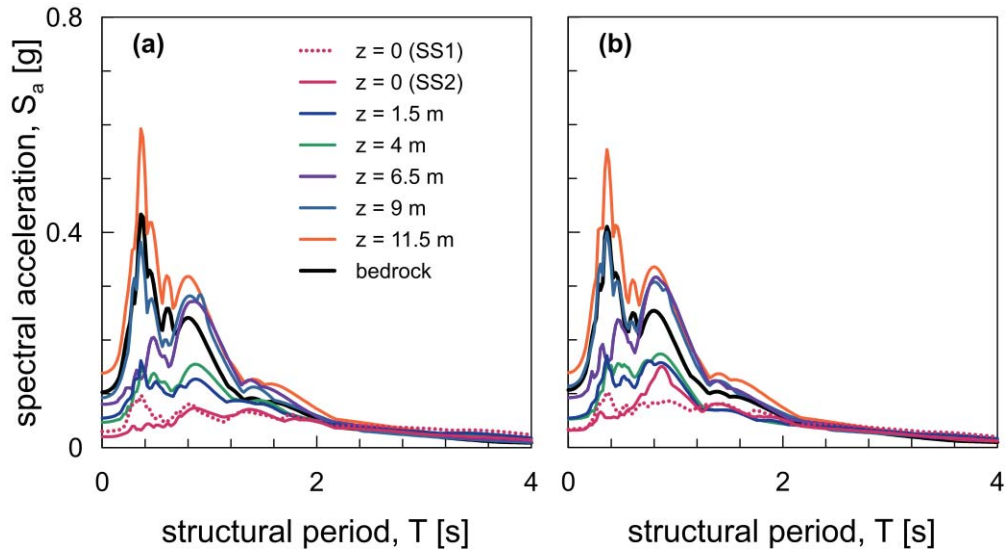

Figure 5: Response spectra along the vertical array for earthquake EQ1 in (a) flight 1 and (b) flight 2.

The top-to-base Fourier amplitude ratio obtained considering both signals at the ground surface are quite similar for both flights 1 and 2, indicating a natural frequency of about 0.2 Hz. Differences in the amplitude of the first peak in flights 1 and 2 reflects the influence of the superstructure in the dynamic response of the system.

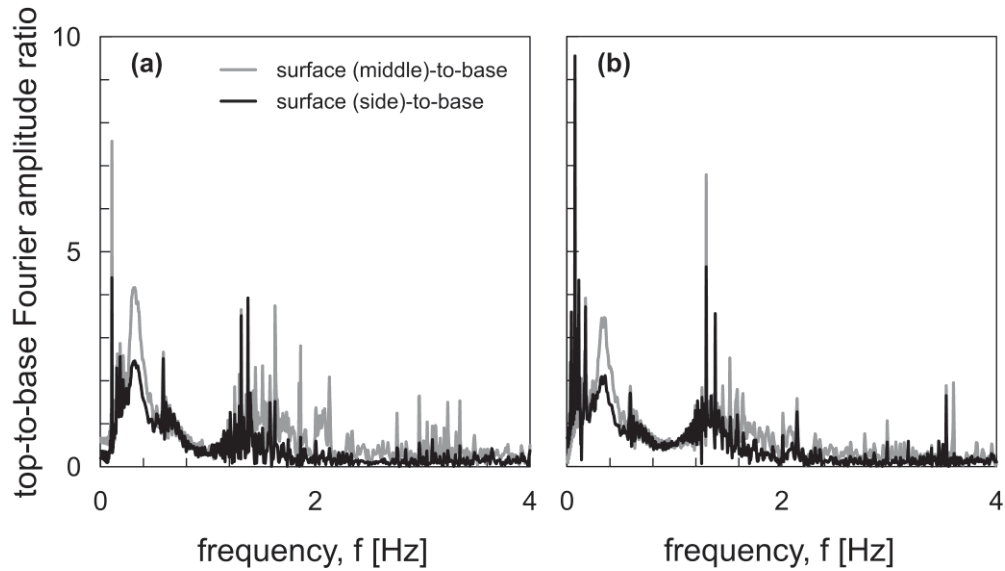

Figure 6: Top-to-base Fourier amplitude ratio obtained under the sine sweep input motion in (a) flight 1 and (b) flight 2.

#### 4 KINEMATIC EFFECTS ON PILE-HEAD RESPONSE

Kinematic soil-pile interaction effects were then explored on pile-head response as recorded during flight 1. To this end, acceleration response spectra computed at the head of the SP or at the cap of the PG1 and PG2 models are compared in Figures 7a and 7b for EQ1 and EQ2, respectively. The corresponding response spectrum at the ground surface (SS2 in Figure 2) is

also plotted. Contrary to the usual belief of a beneficial effect of a fixed-head pile in reducing the amplitude of high-frequency components of the ground surface motion at free-field conditions, the response spectra plotted in Figure 7 show a reversed trend where spectral ordinates at the level of the pile-head are above those of the ground surface motion. Such a behaviour imply that in this particular case of a very soft soil, the actual amplitude of motion imposed at the base of a pile-supported structure may be higher with respect to the amplitude of motion at soil surface, which is traditionally employed in design practice, highlighting a possibly detrimental effect of pile foundations. This observation could possibly be associated to the interpretation given in Iovino et al. [10] that piles average the non-uniform deformation of the surrounding soil along an effective depth which is a fraction of the pile active length. In the case where the non-uniform soil deformation is de-amplified between this effective depth and ground surface (Figure 4) then the averaging action of piles may lead larger amplitudes of motion. However, further elaboration is needed to understand the interaction mechanism in such cases, taking also into account the contribution of the rotational component of the pile-head motion.

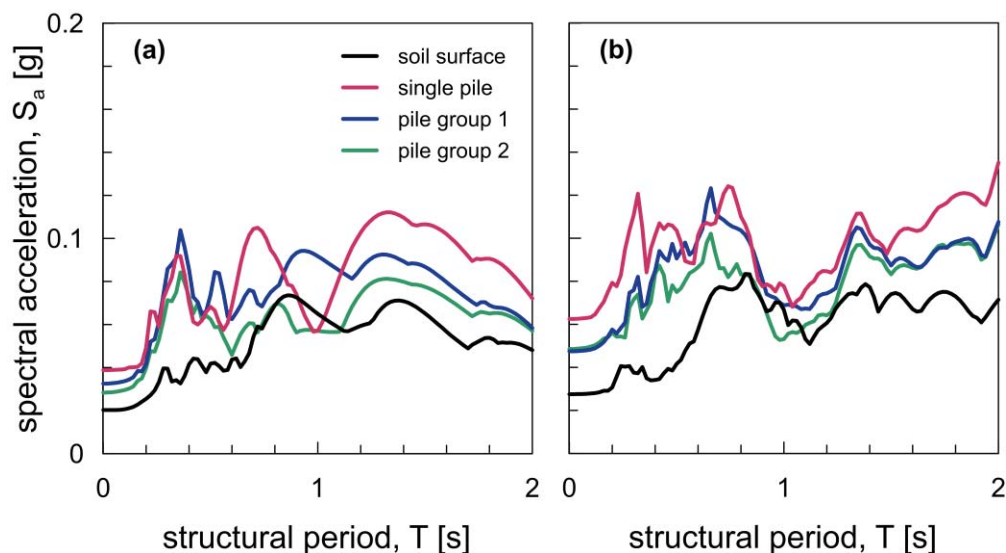

Figure 7: Response spectra for flight 1 during (a) earthquake EQ1 and (b) earthquake EQ2.

## 5 SSI PERIOD OF THE COUPLED SPS SYSTEMS

Mention has already been made that soil compliance may affect considerably the vibrational characteristics of a structure, referring to an elongation of its natural period with respect to the fixed-base case, that may be important in the case of soft soils such as the one employed in the centrifuge tests at hand. In order to identify this aspect by means of the centrifuge records acquired from flight 2, we derived structural top-to-ground surface acceleration response spectra ratios for each coupled system included in the centrifuge apparatus. Results are plotted in Figures 8a and 8b for EQ1 and EQ2, respectively, referring to the SDOF structure supported by the SP, the PG1 and the PG2 foundation models. The period at which this ratio achieves its peak value corresponds to the natural period of the coupled system ( $T_{ssi}$ ), including the effect of soil compliance. It is reiterated that the fixed-base period ( $T_{fixed}$ ) of the SDOF oscillator was measured at 0.2 sec.

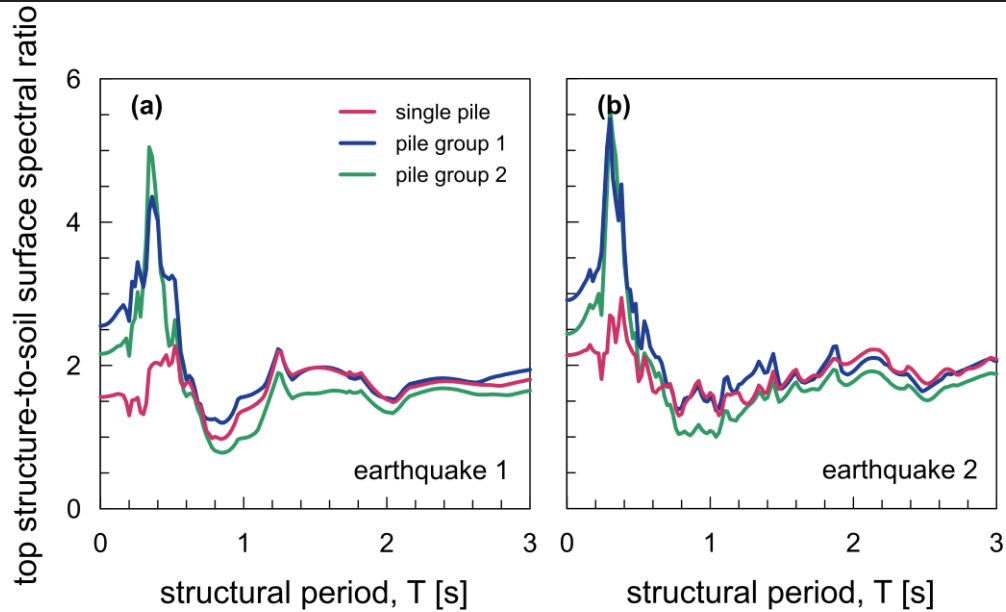

Figure 8: Top structure-to-soil surface spectral ratio obtained from Flight 2 for (a) earthquake EQ1 and (b) earthquake EQ2.

The experimentally-derived values of  $T_{ssi}$  and the corresponding ratios of  $T_{ssi}/T_{fixed}$  are summarized in Table 3 for each case under consideration. It is observed that for both input motions, the role of such a soft soil in controlling the dynamic characteristics of the flexible-supported structures is dominant, as reflected in the large values of the computed  $T_{ssi}/T_{fixed}$  ratios. The effect is understandably more pronounced for the SDOF oscillator supported by the SP foundation model. In this case, the  $T_{ssi}/T_{fixed}$  ratio reaches or even exceeds 2, denoting a very strong effect of soil flexibility on the system period. When the SDOF structure is supported by the pile groups the effect of soil compliance is less pronounced but still quite important, leading to  $T_{ssi}/T_{fixed}$  ratios at 1.5 or higher, which denote a 50% or more of increase of the SSI period with respect to the fixed-base case. It is also noteworthy that the SSI period is almost the same between SDOF-PG1 and SDOF-PG2 systems, indicating a negligible effect of pile cap embedment on  $T_{ssi}$ .

Input motion	Coupled system	$T_{ssi}$ (sec)	$T_{ssi} / T_{fixed}$
EQ1	SDOF on SP	0.46	2.3
	SDOF on PG1	0.36	1.8
	SDOF on PG2	0.34	1.7
EQ2	SDOF on SP	0.38	1.9
	SDOF on PG1	0.30	1.5
	SDOF on PG2	0.30	1.5

Table 3:  $T_{ssi}$  period and ratios of  $T_{ssi}/T_{fixed}$  identified from centrifuge data elaboration of flight 2.

## 6 CONCLUSIONS

Critical aspects of soil-pile-structure interaction in a soft kaolin clay soil were explored under earthquake loading in centrifuge tests carried out at 50g aboard the Turner Beam centrifuge at the Schofield Centre of the University of Cambridge. A single pile and two 3x1 pile groups were modeled in the centrifuge to explore kinematic soil-pile interaction effects on the modification of the soil motion and soil compliance effects on the vibrational characteristics of a SDOF structure. Preliminary analysis of the experimental data revealed the following trends:

- A remarkable attenuation of maximum ground acceleration between base and surface of the soil layer was recorded, showing a substantial filtering effect of soil on the high-frequency components of motion. Such a de-amplification can be attributed to large earthquake-induced shear stresses close to the low shear strength of the particular soft clay, a condition which limits the transmission of the propagating wave field.
- A strong amplification of the motion at the pile-head with respect to that at ground surface was recorded for both earthquake excitations considered in this study, providing evidence that the actual seismic loading imposed at the base of the supporting structure may be higher with respect to the one induced by ground surface motion, which is usually employed in design practice. Further analysis of the centrifuge data is needed to obtain insight on such a behaviour, including the possibly important contribution of the rotational component of the pile motion.
- The experimentally-obtained natural period of the examined SSI systems was increased substantially with respect to the fixed-base case, denoting a dominant effect of the soil compliance in the case of the examined soft clay. For the foundation layouts modeled in the centrifuge, ratios of flexible- over fixed-base period exceeded 1.5, being more pronounced in the case of the single pile with respect to the pile-groups. In the latter case, the effect of the embedment depth on the SSI period was minor.

## ACKNOWLEDGEMENTS

This research has been developed under SERA project COSMO 'Change of Seismic motion due to pile-soil-kinematic interaction' funded within the framework of European Union's Horizon 2020 research and innovation program Transnational Access to SERA, Seismology and Earthquake Engineering Infrastructure Alliance for Europe, Grant Agreement No. 730900.

**Keywords:** Structural Heath Monitoring; Automatic Operational Modal Analysis; Environmental effects; Static monitoring; Frequency veering.

**Abstract.** *The Santa Maria di Collemaggio basilica is a 13th-century masonry masterpiece. The restoration works following the 2009 earthquake in L'Aquila included the installation of a permanent monitoring system. Crack gauges monitor a few significant cracks that appeared during the 2009 earthquake. Force-Balance accelerometers record the dynamic response of the entire structure. The dynamic response to ambient excitation leads to the estimation of the modal parameters. The current paper reports the outcomes of two years of static and dynamic monitoring from 1/1/2018 to 31/12/2019. The authors correlated the outdoor temperature and relative humidity to both the amplitude of the cracks and the modal parameters. The temperature deeply affects the static and dynamic response of the basilica. However, the linear correlations between the temperature and the structural response are diverse. There are cracks which stretch when the temperature rises and cracks which act oppositely. Natural frequencies lower when the temperature rises, while the same modes exhibit modal interaction phenomena. Furthermore, the natural frequencies of the basilica are not stationary but are moderately declining across the years. The basilica is a complex structure, where the different constitutive behaviour of three different materials, masonry, steel and timber may yield a varied structural response. The authors attempt to provide a qualitative interpretation of the observed behaviour, namely the detected correlations to the outdoor temperature, the lowering of the natural frequencies across the years and mode interaction phenomena.*

## 1 INTRODUCTION

Long term monitoring of civil structures belongs to almost thirty years of practice [1, 2, 3]. However, the long term monitoring of large masonry structures has almost ten years of history. After the work by Ramos et al. [4], a few other scholars investigated the static and dynamic behaviour of historical masonry structures: towers [5, 6, 7], cathedrals [4] and palaces [8].

A few research groups, mainly concentrated in the Mediterranean area, dedicated their research efforts to this topic. Concerning the masonry churches, L.F. Ramos et al. [4] and Masciotta et al. [9, 10] monitored the Church of Monastery of Jeronimos. Elyamani et al. [11] monitored the Mallorca cathedral (Mallorca Island, Spain) under ambient sources of vibration and seismic events. A few months ago, Gentile et al. [12] reported on the long-term monitoring of the Milan cathedral, which hosts the most extensive monitoring system ever installed in a cultural heritage monument.

The current paper illustrates the static and dynamic monitoring of the Santa Maria di Collemaggio basilica. Differently from the considered cases, the Church of Monastery of Jeronimos, the Mallorca cathedral and the Milan cathedral, the Santa Maria di Collemaggio basilica suffered the structural consequences of a destructive earthquake in 2009. The monitoring system will allow understanding, not just the correlation of the modal parameters to environmental effects, but the effects of the retrofit interventions.

The University of L'Aquila began the study of the dynamics of the Santa Maria di Collemaggio basilica in 1989. Dozens of scholars studied the basilica from historical [13], archaeological [14], architectural [15, 16, 17, 18], structural [19, 20, 21, 22, 23, 24, 3, 25, 26, 27], geotechnical [28, 29] and even energetic [30] perspectives. The dynamics of the Basilica was investigated by the University of L'Aquila [31, 32, 33, 34, 35, 36]. So far, no study presented the results of long-term monitoring of the Santa Maria di Collemaggio basilica.

After the 2009 earthquake in L'Aquila, the University of L'Aquila, the University La Sapienza in Rome and the Politecnico in Milan supported the design phase of the restoration, supervised by the *Soprintendenza ai Beni Architettonici e Paesaggistici per l'Abruzzo*. A funding agreement, signed by Eni and the municipality of L'Aquila, pointed at developing a paradigmatic model in the panorama of restoration of monumental architectural heritage, based on a multidisciplinary plan. The University of L'Aquila was further commissioned to conceive a monitoring system, which could operate during and after the rehabilitation. In the first working phase, the monitoring system provided the construction manager with a survey tool about structural interventions. After the rehabilitation, the monitoring system was fully-fledged – an essential instrument for the implementation of the conservation plan. The conservation plan aims at assessing the conservation state of the basilica, based on its intrinsic vulnerability and the regional seismic risk.

Moreover, the permanent monitoring system, installed in 2017, aims at supporting research activities which will possibly lead to the assessment of reliability thresholds, damage detection and damage localization. The significant number of accelerometers allows a refined resolution of the mode shapes and may give enough information to reliably estimate the evolution of the structural condition of the basilica, especially after seismic events. The definition of the reliability thresholds is essential in assessing the structural safety based on dynamic data after seismic events.

The paper presents selected results from the long-term monitoring of the Santa Maria di Collemaggio basilica extracted from [37].

## 2 The basilica

Santa Maria di Collemaggio, built at the end of the 13th century, is a large medieval church in L'Aquila, central Italy. It is a world-famous church for its significance in religious history [38]. The elegant Romanesque façade has the appearance of a wall, with a central door, embellished in the 15th century, and two smaller flanking doors; The interior follows the standard plan of a nave and two side aisles, each one divided from it by a row of columns, from which arches support a tall wooden ceiling. The Basilica has a masonry structure typical of ancient buildings in L'Aquila [39], with varied, but prevalently regular, masonry textures [38, 40, 41, 42]. On the lateral wall stands the Holy Door (Fig.1(c)), opened on 28th and 29th of August every year in occasion of the annual jubilee.

The Basilica has a middle nave (61 m long and 11.3 m wide) and two side naves (approx 8 m wide). The central and side naves reach a maximum height of 20.4 m and 15 m respectively, while the facade is 29.5 m wide and 21.3 m high.

Figure 1: (a) Facade, (b) interior, (c) Holy Door, (d) plan of the basilica, (e) prospect of the apse, (f) and the Holy Door wall.

The permanent monitoring system consists of nine crack measurement devices, 78 Force-balance accelerometers (2 triaxial 12 biaxial and 48 monoaxial), and five temperature/humidity sensors.

The crack measurement devices are high precision triangulation lasers with a 25mm measuring range, 0.03mm linearity and  $2.5\mu\text{m}$  reproducibility. The FBA accelerometers are characterized by a 2.5V/g sensitivity. The details of the monitoring system are presented in [37]

## 3 Long term static monitoring

The monitoring devices, placed over significant cracks, have acquired every hour since 31/08/2018. The authors report selected results from 31/08/2018 to 21/12/2019. The behaviour of the cracks suggests the following coarse classification see Tab.1:

- FP2, FP3 and FP7 (Fig.2(b),(c),(g)): The amplitude is almost constant with oscillation between the maximum and minimum amplitudes equal to 0.03 mm, 0.04 mm and 0.06mm respectively.  
FP2 and FP7 are the sole devices which monitor the cracks on the intrados of the ogival arches in the central nave. The amplitude rests constant, likely meaning that the ogival arches are stable against static forces and environmental parameters. FP3 reveals the stability of a crack below a pavilion vault on the right side of the apse.

Table 1: Statistical description of the amplitude of the instrumented cracks from 31/08/2018 to 21/12/2019

Instrument	Crack measurement [mm]			
	Mean	Variance	Maximum	Minimum
FP1	0.11	$7.50 \times 10^{-4}$	0.18	0.06
FP2	0.07	$9.10 \times 10^{-5}$	0.09	0.06
FP3	15.68	$3.67 \times 10^{-5}$	15.69	15.65
FP4	0.71	$5.15 \times 10^{-3}$	0.86	0.57
FP5	1.02	$9.00 \times 10^{-3}$	1.17	0.81
FP6	0.10	$5.21 \times 10^{-4}$	0.16	0.06
FP7	5.73	$1.88 \times 10^{-4}$	5.75	5.69
FP8	0.22	$1.34 \times 10^{-3}$	0.31	0.16
FP8	6.19	$1.99 \times 10^{-2}$	6.42	6.18

- FP1, FP4, FP6, FP8 and FP9 (Fig.2(a),(d),(f),(h),(i)) show higher discrepancies between the minimum and maximum amplitudes, equal to 0.12 mm, 0.29 mm, 0.10 mm and 0.24 mm respectively. The amplitude of these cracks increases during spring and summer and decreases in the cold seasons. These devices measure the amplitude of the cracks in the presbiterion: the right chapel (FP4 and FP8), the apse (FP5, FP8 and FP9) and the left chapel (FP1).
- FP5 (Fig.2(e)) yields a 0.36 mm discrepancy between the two extreme values. However, the amplitude decreases during the cold season and vice versa. FP5 monitors a crack on the intrados of the apse vault.

### 3.1 Environmental effects

The evolution of the amplitudes suggests a season-driven behaviour: the environmental parameters mainly determine the observed oscillations. Unfortunately, the thermoigrometers suffered functioning discontinuities due to the difficulty in promptly replacing the batteries by the owner of the basilica. For this reason, the authors adopted as correlation parameters the outdoor temperature and relative humidity recorded by the CETEMPS, (the Centre of Excellence on Telesensing of Environment and Model Prediction Severe events, see <http://cetemps.aquila.infn.it/>) in L'Aquila. Fig.3(a)-(b) show the minute by minute evolution of the temperature and relative humidity from 1/1/2018 to 31/12/2019. The relative humidity has a scattered behaviour; a red line follows the averaged trend obtained from a moving average over a thousand samples. Fig.4 illustrates the correlation between the crack amplitudes and the temperature. The correlations to temperature confirm three trends, already remarked in the previous paragraphs. (i) An almost stationary behaviour in FP2, FP3 and FP7; (ii) A positive rate in FP1, FP4, FP6, FP8 and FP9; (iii) A negative rate in FP5.

The two opposite trends may descend from opposing kinematic mechanisms, which can determine the closing or stretching of the cracks when the masonry swells from thermal expansion. Except for FP9, which is placed outside the apse, the other devices are inside the basilica. Two kinematic mechanisms may stand behind the identified correlations.

The temperature is not constant across the wall thickness. During summer, the outer layers have higher temperature values than the inside ones, and vice versa during winter: likely, a 15°C temperature difference between the outer and inner wall layers occurs during summer and an opposite 15°C difference during winter. The thermal gradient may yield the curvature of the wall, see Fig.5: the external crack stretches ( $l_1$ ), while the internal one reduces ( $l_2$ ). By assuming a thermal expansion coefficient equal to  $\alpha = 5 \times 10^{-6} [^\circ\text{C}^{-1}]$ , and a  $\Delta T = 30^\circ\text{C}$  gradient,

Figure 2: Variation of the cracks amplitudes measured from 31/08/2018 to 21/12/2019. The drops in FP1, FP4, FP5 and FP8 derive from almost one month interruption, indicated by a dashed vertical line.

Figure 3: Variation of the environmental parameters measured from 1/01/2018 to 31/12/2019: (a) Outdoor temperature; (b) Outdoor Relative Humidity; The red line is the moving average over a thousand samples.

Figure 4: Correlation between the crack amplitude and the outdoor temperature (from 31/08/2018 to 21/12/2019).

obtained by summing the absolute gradients of summer ( $\Delta T_s = 15^\circ\text{C}$ ) and winter ( $\Delta T_w = -15^\circ\text{C}$ ), the equivalent thickness  $t_{eq}$  associated to the maximum drifts are approximately between 0.8m and 2m, see Tab.2, according to the following equations:

$$|\Delta x|_{max} = |\Delta x_s| + |\Delta x_w| = t_{eq} \alpha (|\Delta T_s| + |\Delta T_w|) \quad (1)$$

$$t_{eq} = \frac{\Delta x_{max}}{\alpha \Delta T} \quad (2)$$

where  $t_{eq}$  is the equivalent thickness,  $\Delta x_{max}$  the relative movement of the crack during the year, obtained by summing the effects of summer  $\Delta x_s$  and winter  $\Delta x_w$ ,  $\alpha$  the thermal expansion coefficient and  $\Delta T$  difference between the outdoor temperature during summer and the indoor temperature during winter. Tab.2 reports the equivalent thickness related to the devices which

Figure 5: kinematic mechanism possibly associated to the crack behaviour.

measured relative displacements higher than 0.1mm. The identified values match with the wall

Table 2: Estimate of the equivalent wall thickness associated to the maximum relative displacement measured by the crack monitoring devices.

Instrument	Max displ. [mm]	$\alpha$ [ $^\circ\text{C}^{-1}$ ]	$\Delta T$ [ $^\circ\text{C}$ ]	Equiv. Thickness [m]
FP1	0.12	$5 \times 10^{-6}$	30	0.80
FP4	0.29	$5 \times 10^{-6}$	30	1.93
FP5	0.36	$5 \times 10^{-6}$	30	2.40
FP8	0.15	$5 \times 10^{-6}$	30	1.00
FP9	0.24	$5 \times 10^{-6}$	30	1.60

thicknesses corresponding to the measurement devices and possibly validate the elementary kinematic mechanism assumed in Fig.5.

The simple calculations in the above paragraphs have the sole objective of a crude understanding of the results. The equivalent thickness is not the physical thickness of the wall. Besides, the real thickness of masonry is not constant, since most of the cracks stand in the vaults, which were reinforced and filled with expanded clay during the retrofitting interventions: the thickness of the vaults depends on the collaboration between the structure and the filling material. For this reason, the authors preferred to check the amounts of the obtained results, which are on average compatible with the actual masonry thicknesses and, consequently, they possibly descend from the sole thermal effects, rather than other phenomena.

#### 4 Dynamic monitoring

The section presents the outcomes of long-term dynamic monitoring. The first part introduces the results of dynamic identification in terms of mode shapes, natural frequencies and viscous damping. The following parts collect the natural frequencies and MAC (Modal Assurance Criterion) values identified from all time-series and relate them to the outdoor environmental parameters: temperature and relative humidity.

#### 4.1 Dynamic identification

The authors developed an automatic processing algorithm, implemented in MATLAB, based on the Stochastic Subspace Identification (SSI)-cov method [43, 44, 45, 46, 47]. The method yields an estimate of the modal parameters from the acceleration time-series recorded in operational condition.

A factor  $N_d=20$  decimates the initial sampling frequency equal to 250Hz. [37] details the automatic identification algorithm.

#### 5 The dynamics of the nave walls

The dynamic identification of the nave walls returns four stable modes. The authors report the averaged natural frequencies values up to the first decimal place. The higher decimal places will be discussed in light of long-term monitoring. The first mode at 2.09Hz (Fig.6(a)) interests the displacement of all measurement points in the same direction. The displacement is consistently low in the apse comparing to the nave walls motion: the apse is very rigid compared to other parts of the basilica. The particular mode shape possibly originates from the Cross Laminated Timber (CLT) ceiling, behaving like a rigid diaphragm which imposes the same displacement to the nave walls summits.

The higher modes affect the bending of the nave walls. The second mode at 3.11 Hz (Fig.6(b)) mainly regards the change of direction along the vertical: the measurement points by the top of the columns move oppositely to those by the CLT ceiling. Moreover, the phases of the two nave walls are opposite. The third mode at 3.27 Hz (Fig.6(c)) mainly concerns the change of direction of the measurement points along the x-direction, like a second bending mode. The fourth mode at 3.82 Hz (Fig.6(d)) is quite twisted: it is a sort of third bending mode shape. Tab.3 reports the cross MAC between the identified modes in Fig.6. The terms out of the main diagonal are shallow: the mode shapes are dissimilar between each other and distinctly identifiable.

The apse is quite massive, and participate to the identified mode shapes with much lower deformation than the other structural members due to its significant stiffness. The investigation of the apse dynamics requires dedicated efforts and will be the object of future studies by the authors. The dynamic identification carried out before the restoration by [31] evidenced four modes (see

Table 3: Cross MAC between the identified mode shapes.

	2.09	3.11	3.27	3.82
2.09	<b>1</b>	0.04	0.009	0.004
3.11	0.04	<b>1</b>	0.006	0.004
3.27	0.009	0.006	<b>1</b>	0.151
3.82	0.004	0.004	0.151	<b>1</b>

Tab.4), resembling the ones in Fig.6 with the following natural frequencies: 1.25, 1.72, 2.35

Table 4: Evolution of the natural frequencies, before and after the 2009 earthquake and, after the restoration.

	Before 2009 [31]	Since 2017
1st mode [Hz]	1.25	2.09
2nd mode [Hz]	1.72	3.11
3rd mode [Hz]	2.35	3.27
4th mode [Hz]	2.44	3.82

Tab.4), resembling the ones in Fig.6 with the following natural frequencies: 1.25, 1.72, 2.35

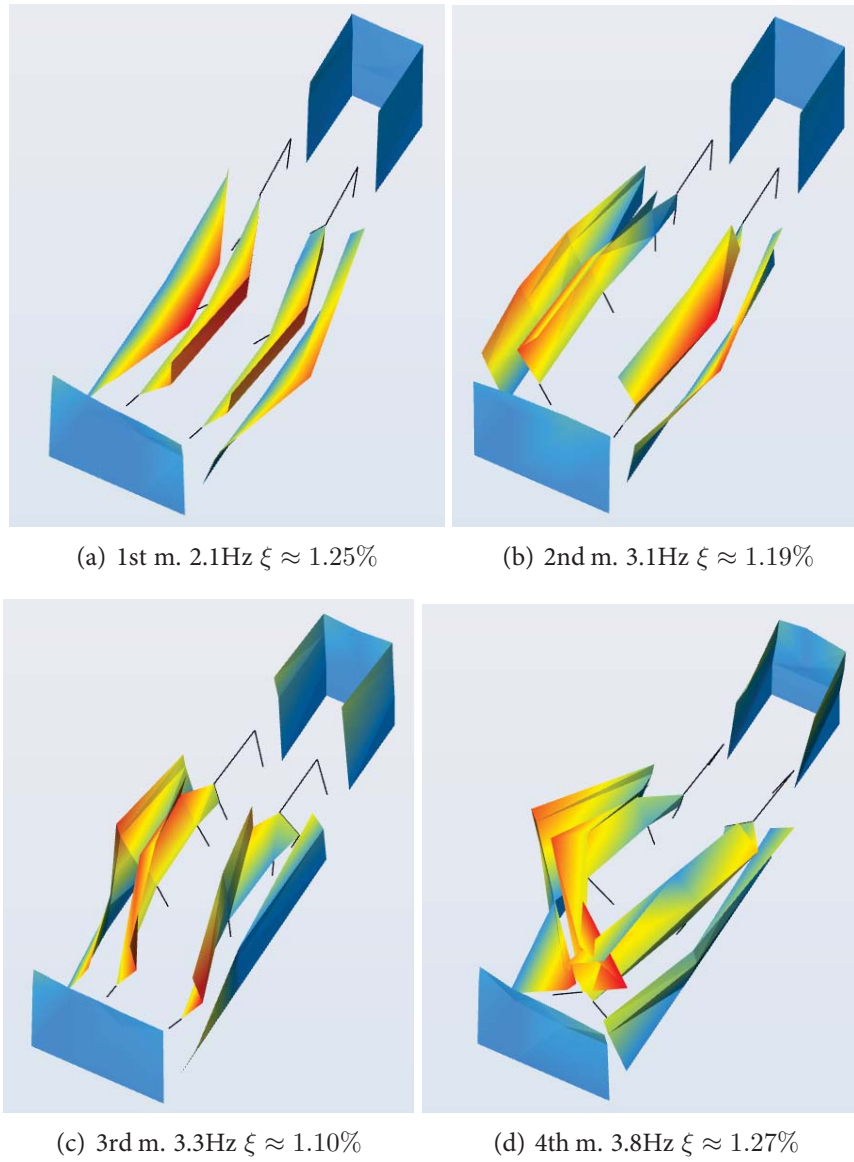

Figure 6: Illustration of the mode shapes of the nave walls, where m. stands for mode and  $\xi$  is the average modal damping.

and 2.44 Hz. The structural interventions following the 2009 earthquake produced meaningful differences on the corresponding natural frequencies, which have increased of 66.80%, 80.99%, 39.15% and 59.35% respectively; the average increment of the current four natural frequencies is approximately 60.82%, compared to the structural behaviour before the 2009 earthquake. The identification in operational condition, based on the current measurement set-up, marks a significant localization in the mode shapes, i.e. many mode shapes show significantly higher displacement in some parts rather than in others. As illustrated in Fig.6, the modes between the 1st and the 4th (2.1 – 3.8 Hz) affect almost exclusively nave walls. Although the basilica can be considered as an elastic continuum, the localization of deformation produces the potential uncoupling of the macroelement responses, which are the facade and the nave walls. The localization of deformation might encourage the implementation of predictive reduced-order models for the facade and the nave walls.

### 5.1 Long-term monitoring

The natural frequencies identified from each set of time-series are concatenated and reported in Fig.7. Tab.7 evidences two concurring trends: the natural frequency oscillates between seasons; The natural frequencies are lightly decreasing in the entire period. The first observation is in full line with the finding by [4, 10, 7, 48]: the environmental parameters sensibly affect the natural frequencies. However, to the authors' knowledge, the second aspect does not occur in any case study. Tab.6 shows the maximum and minimum values of the linear correlation

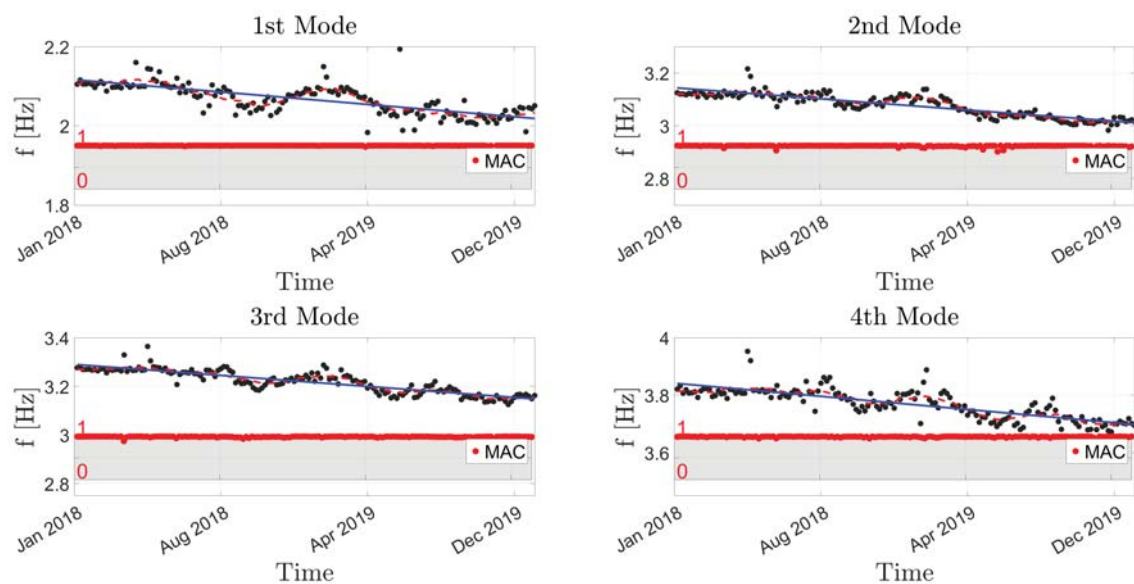

Figure 7: Variation of the natural frequencies and MAC of the detected modes during the investigated period. Red dashed line represents the moving mean of the samples, reflecting frequencies seasonal variation, blue straight interpolating line indicates its general decrease over time. The MAC values refer to a fixed set of modes corresponding to the recordings of 1/1/18.

reported as a solid line in Fig.7. The natural frequencies of the nave walls exhibited a 0.1 Hz decrement. There are no detectable variations of the mode shapes: the MAC values, estimated to a reference set of mode shapes, stand approximately constant and close to 1, see Fig.7. The nave walls, which are bound together by the top CLT roof, are anchored to the nave walls and the facade by threaded steel bars.

The reason of this decrement may derive from the behaviour exhibited by the constituent mate-

Table 5: Statistical description of the frequency and MAC values.

Mode	Frequency [Hz]		MAC	
	Mean	Variance	Mean	Variance
1st	2.07	0.002	0.99	$5.793 \times 10^{-4}$
2nd	3.08	0.002	0.99	$4.408 \times 10^{-4}$
3rd	3.22	0.002	0.99	$1.502 \times 10^{-4}$
4th	3.77	0.002	0.99	$1.046 \times 10^{-4}$

Table 6: Decrease of the natural frequency according to the linear regressions in Fig.7.

Mode	$f_{in}$ [Hz]	$f_{fin}$ [Hz]	$\Delta f$
1st	2.12	2.02	-0.10
2nd	3.14	3.01	-0.13
3rd	3.29	3.15	-0.14
4th	3.84	3.69	-0.15

rials over time. While masonry and steel do not exhibit a sensible decaying of their mechanical properties (especially in two years), it is more likely that the mechanical properties of the Cross-Lam Timber (CLT) roof are stabilizing. In the authors' opinion, the effect which may justify the observed phenomenon is microcracking due to wood drying and thermal expansion constrained by the steel anchoring [49].

## 5.2 Environmental effects

The natural frequencies are correlated to the outdoor temperature and the relative humidity. As already noticed in the long-term static monitoring, the relative humidity does not yield significant correlations, see Fig.9. Conversely, the temperature values return good correlations, evidenced by the linear fitting in Fig.8.

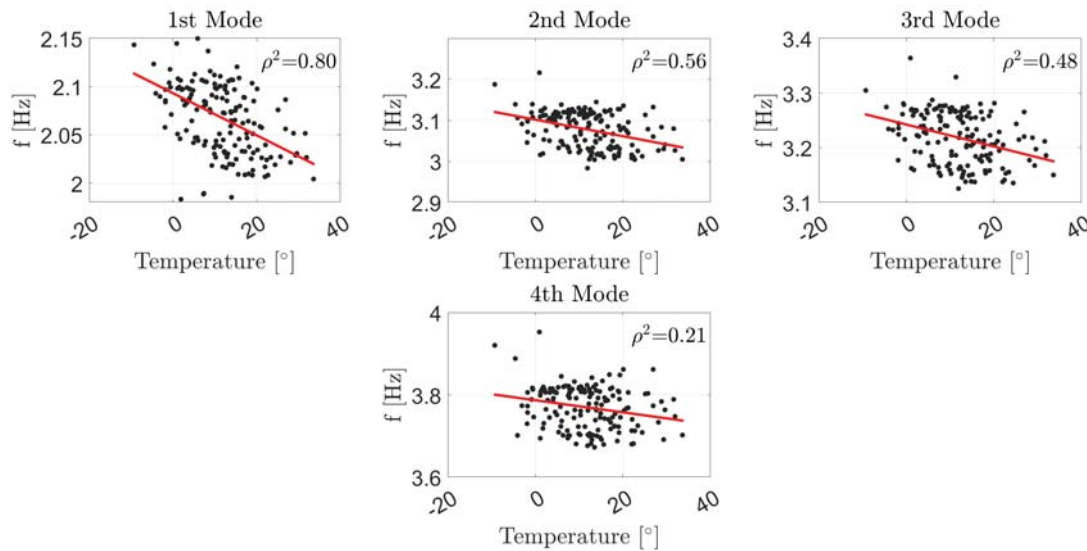

Figure 8: Correlation between the natural frequencies of the identified modes and the outdoor temperature (from 1/01/2018 to 31/12/2019).

To the authors' knowledge, the negative dependence of the natural frequencies to the outdoor temperature was observed in two sole cases: the Milan cathedral [12] and the Consoli Palace

in Gubbio [8]. According to Gentile et al. [12], the negative frequency-temperature correlation in the Milan Cathedral originates from the structural arrangement, consisting of double vault system constrained by an extended net of metallic tie-rods.

Kita et al. noticed a negative correlation [8] between natural frequencies and temperature in the Consoli Palace. The marked increase in natural frequencies of the global vibration modes of the Palace with decreasing ambient temperature has been attributed to an increase in global structural stiffness due to strengthening effects of metallic reinforcements (tie rods shortening at lower temperatures) and the presence of a moderate structural damage state in the Palace.

In the current case, the Santa Maria di Collemaggio basilica has a CLT roof which likely experiences significant thermal expansions and contractions. It acts bonding together the nave walls and provides a significant in-plane stiffness to the roof. The negative frequency-temperature correlations could originate from a decrease in global structural stiffness due to the expansion of the CLT roof at higher temperatures.

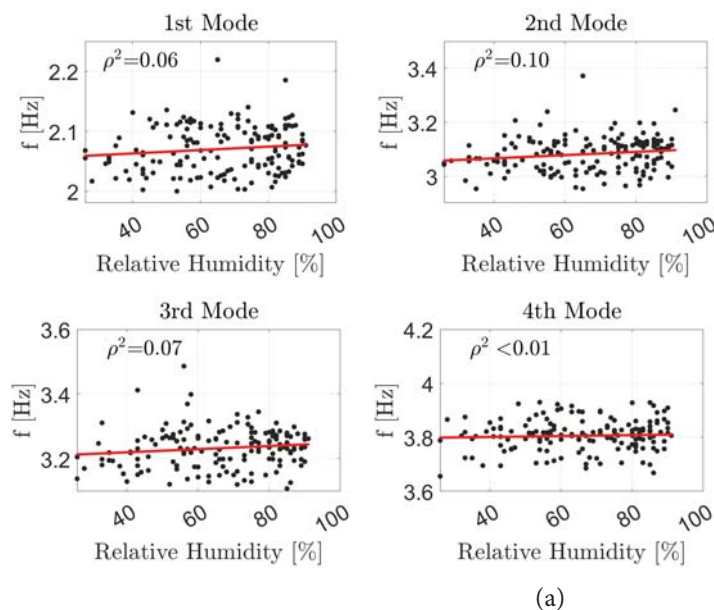

Figure 9: Correlation between the natural frequencies of the identified modes and the outdoor Relative Humidity (from 1/01/2018 to 31/12/2019).

The authors further estimated the temperature effects on the mode shapes. Accurately, the cross MAC between the mode shapes identified from all recordings are related to the outdoor temperature, as illustrated in Fig.10. The inspection of Fig.10 proves the substantial time invariance of the mode shapes. The crack amplitude was not correlated to the natural frequencies. The sole cracks on the nave walls do not change significantly, see Fig.2. The other cracks mainly gather in the apse and the vaults chapels, which, as remarked, participate with lower deformation to the monitored mode shapes.

### 5.3 Discussion

The most significant result regards the moderate but continuous decay of the natural frequencies over time. Likely, the observed decay will converge towards a stationary value, although the experimental data acquired so far are insufficient to formulate a reliable forecast. Data collected during the years will gradually enhance the reliability of the forecast and allow thoughtful

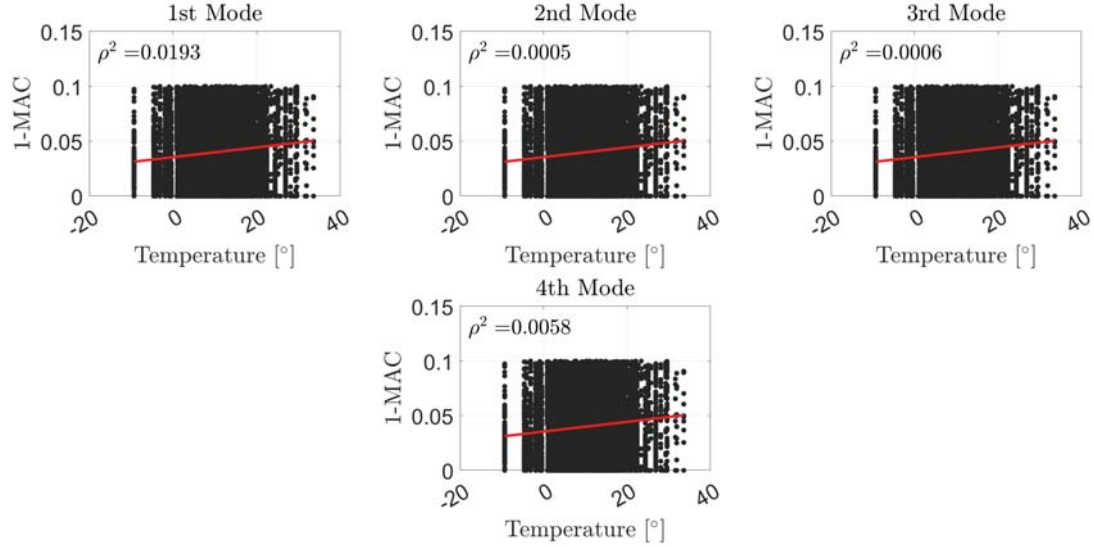

Figure 10: Correlation between outdoor temperature and (1-MAC) of identified modes (from 1/01/2018 to 31/12/2019).

judgment.

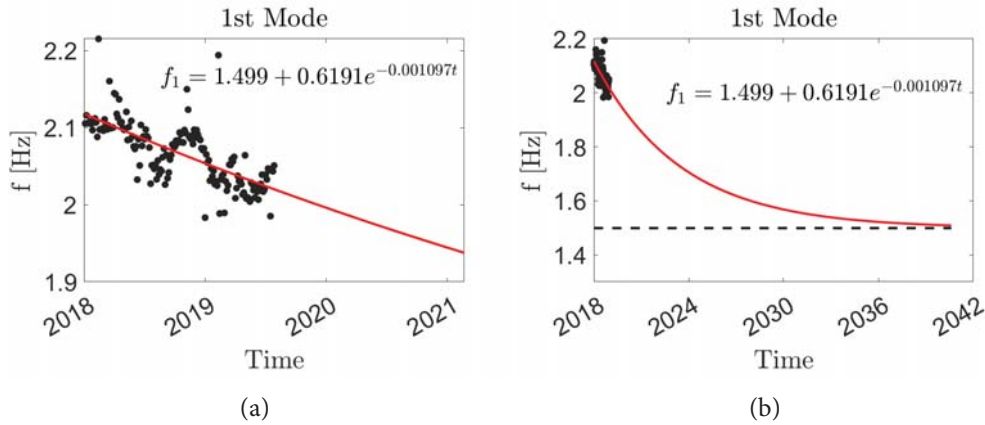

Figure 11: (a) Detail of the exponential fitting of the first natural frequency; (b) Exponential fitting of the first natural frequency extrapolated to a 24 years period.

The authors estimated the optimum exponential fitting of the first natural frequency using the Lovemberg-Marquardt algorithm [50], see (Fig.11):

$$f_1 = 1.499 + 0.6191e^{-0.001097t} \quad (3)$$

The sole material, among those used in the restoration, which has time-dependent mechanical properties in the first life period is timber [51, 52, 53]. The mechanical properties of the CLT roof may be stabilizing due to the actual environmental conditions: the CLT roof was installed in 2017. The considered two-years period is too short to derive plausible convergence values. The analysis has a qualitative and illustrative character, aiming at explaining the possible future scenarios. The reported exponential decay suggests that this effect will extinguish in an almost 20 years period since the CLT installation in 2017.

However, a mechanical interpretation of the obtained results requires a numerical model of the basilica, which allows determining the possible percentage decrease of the CLT roof stiffness congruous with the experimental findings. Further, additional instrumentation of the roof would enlighten on the structural behaviour of the timber members.

## 6 The dynamics of the facade

### 6.1 Modal identification and long-term monitoring

The fifth sixth and seventh modes mainly involve the facade, rather than the nave walls (Fig.12). They are all characterized by out-of-plane displacements most visible in the upper part, free, at their rear, from the nave walls constraints.

The fifth mode, at 4.5 Hz (Fig.12(a)), shows the bending of the facade by the rose window, while the modal components given by the sensors at the top edges have the same directions.

The sixth mode at 4.8 Hz highlights the phase opposition of the displacement of the two upper edges of the facade and a deflection above the portal (Fig.12(b)).

The last identified mode is similar to the fifth. The main difference lies in a shallow deflection occurring by the middle of the facade.

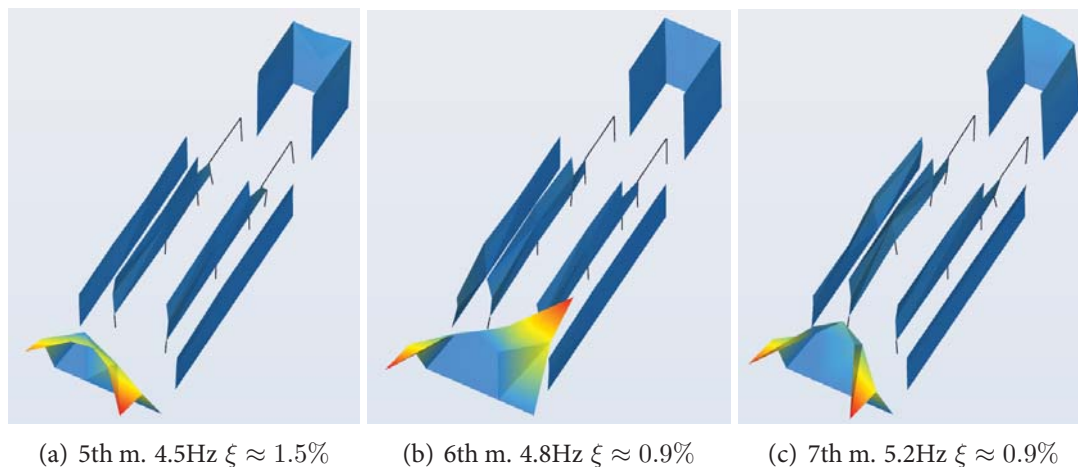

Figure 12: Illustration of the facade mode shapes, where m. stands for mode and  $\xi$  is the averaged modal damping.

Fig.13 presents the results of the modal tracking of the modes associated with the facade. The authors found the same trends found in the previous modes: the seasonal fluctuation of frequencies and their slight decreasing over time. However, the seasonal fluctuations are more marked than those in the previous modes.

Tab.8 shows the maximum and minimum values of the linear correlation reported as a solid

Table 7: Statistical description of the frequency and MAC values.

Mode	Frequency [Hz]		MAC	
	Mean	Variance	Mean	Variance
5th	4.38	0.016	0.92	$6.30 \times 10^{-3}$

6th	3.14	3.01	-0.13
7th	3.29	3.15	-0.18

## 6.2 Modal interaction

An impressive phenomenon affects the fifth and seventh modes: not solely their natural frequencies decrease during the hot season, but their shape and the mutual distance between the frequencies do change during the year, almost cyclically in both the years under investigation. In order to better understand what happens, dates belonging to two different seasons have been compared: as evidenced by Tab.9, the frequencies vary between 3% and 8% among January and September.

The MAC between modal shapes proves a similarity between the 5th mode of September and

Table 9: The identified frequencies in January and September, 2019.

Mode	Jan	Sept	$\Delta f$ (%)
5th	4.43	4.28	-3.3
6th	4.82	4.43	-8.0
7th	5.14	4.85	-5.6

the 7th mode of January and vice versa (Tab.10). The sixth mode does not seem to be affected by changes in shape.

Fig.14 shows the one-year variations of the 5th and 7th natural frequencies, adimensionalized

Table 10: MAC evaluated between the modes of the facade identified in January and in September, 2019.

Mode	5th <sub>Jan</sub>	6th <sub>Jan</sub>	7th <sub>Jan</sub>
5th <sub>Sept</sub>	0.685	0.002	<b>0.901</b>
6th <sub>Sept</sub>	0.130	<b>0.905</b>	0.150
7th <sub>Sept</sub>	<b>0.689</b>	0.266	0.567

to the fifth mode, compared to the temperature values. The increase in temperature, typical of the summer season, leads the frequencies to approach each other.

The mode shapes change during the year: the two mode shapes mutate until reaching the

Figure 14: Evolution of the fifth and seventh natural frequency, adimensionalized to the fifth. The dash-dot line interpolates the data associated with the seventh mode. The pictures of the mode shapes correspond to the dates indicated. Below, the trend of temperatures in the same period. Data correspond to acquisitions recorded at the same hour (2 pm) between January and September, when temperature progressively rises.

maximum similarity in June, and then they exhibit the complete shape inversion between August

and September, in which temperature attains the highest values.

Subsequently, the arrival of the cold season determines the reversed process: both the mode shapes return to their starting states.

The phenomenon is strongly related to temperature: the variation of the two mode shapes is synthetically described by introducing the  $R$  parameter, defined as

$$R = \frac{d_{F9}}{d_{F5}} \quad (4)$$

The parameter represents the ratio between the out-of-plane mode components in points  $F9$ , on the left top of the facade, and  $F5$  on the opposite side. Fig.15 shows the value of the  $R$  param-

Figure 15:  $R$  Ratio evaluated for both the 5th mode (blue) and the 7th (red).

eter associated with the 5th and the 7th modes, which have opposite temperature correlations. The intersection of the two interpolating lines identifies a value of  $R$  approximately equal to one, meaning that the modal displacements of the two upper edges of the facade coincide, for both modes. The abscissa of the intersection point marks a temperature of about 20 degrees, attributable to that recorded in June.

The trend of frequencies of the 7th mode evidences a slight increase at the end of August, while the temperature still increases.

Although samples recorded in this month are too scarce to yield a sound validation, the overall phenomenon partially resembles that of mode interaction typical of frequency veering, well known in structural dynamics [54].

In the authors' opinion, this particular behaviour could be due to local effects related to the influence of temperature on the elastic parameters of the structure.

## 7 Conclusions

The paper presents the results of two years (2018-2019) static and dynamic monitoring of the Santa Maria di Collemaggio basilica. The masonry structure, severely damaged by the 2009 earthquake in L'Aquila, was rehabilitated and reopened in 2017. The restoration included the installation of a monitoring system consisting of 78 Force Balance accelerometers and nine crack monitoring devices. The authors mainly focused on the estimate of the modal properties and the effect of the environmental parameters. Here follow the main results of this study:

1. Seven modes have been detected in the frequency range 0-5.5 Hz, identified in operational condition using the SSI-cov algorithm [43]. The identification based on the current measurement set-up, denotes a notable localization in the mode shapes, i.e. many mode shapes show significantly higher displacement in some parts rather than in others. The first four modes (2.1 – 3.8 Hz) affect almost exclusively nave walls. Conversely, the following modes (4.5 - 5.3 Hz) affect the facade and negligibly the nave walls.
2. The authors implemented an automatic algorithm to identify the modal parameters and track their evolution over time. The natural frequencies are decreasing over time: In two years, there has been an almost 0.1 Hz frequency decrement. It possibly derived from the moderate in-plane stiffness decaying of the Cross Lam timber roof due to superficial microcracking (wood drying and constrained thermal expansion, e.g.).
3. The modal tracking process of the modes mainly affecting the facade evidenced a phenomenon resembling frequency veering and mode interaction. It strongly depends on temperature: the frequencies of the two modes approach to each other with increasing temperature and their shapes interchange cyclically over time. Despite this, the algorithm was able to perform the tracking process. Other mode shapes do not experience meaningful seasonal variations and are substantially time-invariant.
4. The outdoor temperature drives the observed fluctuation of the natural frequencies. The first four modes have negative temperature-frequency correlations. This effect could arise from a decrease in the global structural stiffness due to the expansion of the CLT roof at higher temperatures. For modes mainly involving the facade, frequency variation due to temperature is amplified by the phenomenon of frequency veering.
5. The outdoor temperature mainly drives the crack evolution. In most cases, the devices revealed positive temperature-amplitude correlations. In a single case, the authors noted the opposite trend. The two behaviours possibly originate from the difference between the outdoor and indoor temperature. The thermal gradient enhances the curvature of the wall, yielding stretching or closing of the cracks depending on their position across the wall thickness.

This paper mainly focuses on the dynamic monitoring of the nave walls and the facade. Future developments will deal with the dynamics of the apse and transept. The present analyses are preliminary to the developing of a probabilistic model of the modal response of the basilica within a Structural Health Monitoring program.

## 8 Acknowledgments

The authors thank Eni, for having financed the restoration of the basilica and the monitoring system, Prof. Dante Galeota as Representative of the University of L'Aquila in the restoration committee, Dr Felice Fusco for his contribution in the design phase of the monitoring system, Prof. Roberto Aloisio to be intermediary with the CETEMPS, and the CETEMPS itself, the centre of excellence on telesensing of environment and model prediction severe events (<http://cetemps.aquila.infn.it/>) of the University of L'Aquila, which provided us with the environmental parameters. The authors further acknowledge the availability of the SolGeo s.r.l. for the maintenance needs.

### Abstract

*The dynamic test in situ of existing bridges is a very promising solution for assessing a reliable model, since it is more convenient than a load test requiring to organize the trucks and close the use of the infrastructure for a longer time. However its effectiveness depends on the test technique, the number, type and location of the sensors, but also on the numerical model that have to allow the introduction of the real boundary conditions. Clearly the dynamic identification of the structural behavior can be also the first step of a monitoring process to check the health of the construction during the time, therefore its effectiveness is fundamental.*

*In this paper the first results of the structural identification based on an ambient vibration test of an existing prestressed concrete bridge are presented. The selected case study is a bridge designed by Riccardo Morandi in 1952-1955 with the emerging technique of Prestressed Concrete (PC).*

*An important step of the process is the developing of the model through a survey and a wide investigation campaign, but also the role of the knowledge of the original design is highlighted due the complexity of the structure.*

**Keywords:** Prestressed bridge, Dynamic test, Model updating, Finite element analysis, Operational Modal Analysis.

---

## 1 INTRODUCTION

Structural identification for assessing and ensuring the safety and integrity of bridge structures is gaining much attention among researchers, due to the more frequent failure of bridges [1, 2], and also considering the existing heritage, in many countries near to the end of its service life.

Currently the dynamic tests are gaining increasing importance and efficiency especially to calibrate reliable numerical models [3-4] useful for a structural analysis, or to start a damage monitoring by two approaches. In one case the monitoring is carried out by the numerical model upgrading [5-7] in the other case a direct analysis of the signals [8-9].

It is noted that the first procedure is certainly more efficient and of great potential since a numerical model allows to investigate in detail the causes of a possible variation of the structural response [10-11], and then can be used to investigate the load-bearing capacity [12-13], its structural behavior under traffic [14] or seismic excitation and the efficiency of a prospective reinforcement interventions. However, the type and uncertainties of the model influence the process and the computational work is heavy.

In this paper the procedure of the structural identification is proposed underlining the various steps that contribute to individuate the real in-situ boundary conditions and the degradation of the construction through the variation of the elastic dynamic response [15-16]. The ambient vibration test (AVT) is carried out due to the simple applicability, albeit it is generally less effective than harmonically forced tests [17]. A brief review of testing methods for bridges explaining their advantages and limitations was presented by Salawu and Williams [18].

Moreover many researchers demonstrated that the environmental actions are able to excite the most significant modes of vibration in the low range of frequencies for flexible systems like cable-stayed bridges [19-20], large span arch bridges [21-22] and suspension bridges [23]. The bridge considered herein is particularly interesting because the static scheme and the technology adopted by Riccardo Morandi in his design was innovative and ambitious at the time but still currently the construction is complex and its analysis requires a detailed finite element model (FEM) that is useful to assess through tests in situ. Furthermore the real boundary conditions have to be assessed to better address the future design of strengthening interventions.

## 2 OVERVIEW OF THE BRIDGE

The case study bridge (Fig. 1), erected in Benevento and designed by Riccardo Morandi in early '50, although not so large, has a great importance since it connects two parts of the city crossing the creek San Nicola that goes through a valley with instable hillsides.

Figure 1: Current lateral view of San Nicola bridge.

A detailed analysis of its conceptual design is reported in [24] evidencing a careful process of optimization by adopting an innovative method of construction with pre-casted segments.

The deck of San Nicola bridge is made of prestressed concrete cast in site with piers and foundations made of reinforced concrete. The static scheme is a portal frame composed by one main span 80.0 m long and two cantilevers of 20.0 m long as shown in Fig. 2.

Fig. 2: Longitudinal scheme of the bridge.

The bridge deck is supported by two piers 9.40 m high; each pier, as shown in Fig. 3, was realized by eight columns of rectangular section, 40.0 cm thick and variable width from 1.50 m at the base to 4.00 m at the top, that are transversally connected at the base and top by a transverse beam.

Figure 3: Transversal and frontal view of the pier.

The piers are linked to the foundations underneath by hinges made of steel rebars to avoid bending moments on the foundation that have to also contain the thrust; in fact, the foundations also act as abutments.

The deck consists of a multicellular caisson whose webs vary in thickness, from a minimum of 13 cm at the midspan, to a maximum of 30 cm at the supports (see Fig. 4). Moreover, the deck shows varying-depth through the spans (beam with curved intrados), which characterizes an approximately linear shape giving also a beneficial arch effect. The depth of the deck cross section varies from a maximum of 3.60 m at the pier supports, to a minimum of 1.60 m at the ends of cantilevers and 2.70 m at the midspan.

The deck is characterized by internal tendons, symmetrical about midspan. The prestressing steel cables are composed of 27 aligned wires with diameter of 5mm and are placed along a straight line in the top slab where the bending moment shows negative values and in the bottom slab in the midspan, but also curved cables are installed along the entire bridge. A portion of the original drawing with the prestressing cables is reported in Fig. 5.

Figure 4: Cross sections of caissons at the midspan (left) and the supports (right).

The upper slab is 9.00 m width and consists of two traffic lanes, 7.00 m width, and two sidewalks 1.00 m width each one. Also the thickness is variable from 13 cm (in the area of the central span where there are no top cables) to 20 cm.

Figure 5: Original drawing with the prestressing cables

### 3 SURVEY AND MATERIAL CHARACTERIZATION

An extensive survey campaign, including surveys, essays and destructive tests on materials, i.e., concrete, steel reinforcement and prestressing steel cable, was carried out.

The geometric survey of the elements forming the deck and the piers shows that the structure was realized quite as designed.

Several essays were carried out on the deck highlighting the concrete cover degradation due to the disposal of the water, especially inside the multicellular caisson, however, no cracking is visible. The good conditions of the ducts and cables were detected except in specific parts where water stagnates. Pier and abutments concrete and reinforcements were also investigated pointing out a concrete surface degradation but limited corrosion of the steel re-bars.

Regarding the materials, 14 cores were taken for the assessment of the compressive strength of the concrete. An average cubic compression strength ( $R_{cm}$ ) of 39.21 MPa and 54.21 MPa have been obtained for pier and deck, respectively. These average values were used to calculate the elastic modulus adopted in the model, described in section 4.

Also samples of prestressing steel cables were taken and tested in the laboratory but the elastic modulus of the steel is assumed from the literature.

### 4 THE IN-SITU DYNAMIC TEST

The AVT was chosen as dynamic test because it doesn't require any additive equipment and affects the use of the bridge for few time.

The dynamic behavior of the bridge has been analyzed by means of a preliminary numerical finite element model, described in the next section to establish the layout of the sensors shown in Fig. 6 that involved the choice of 30 measuring points.

In order to identify both the bending, in plane and out-of-plane, and torsional modes, sensors were arranged in pairs at the long sides of the roadway with a distance of 6 m along the cantilever and 10-12 m along the center span.

The adopted instrumentation consists of five triaxial piezoelectric accelerometers with MEMS technology, characterized by an integrated 24-bit A/D converter of the Sigmadelta type. The sensors sample at a preset frequency of 1024 Hz, transmitting the acquired signal directly to an acquisition unit, characterized by an industrial PC with a preinstalled Linux system.

Figure 6: The layout of sensors in the dynamic test

Since only 5 accelerometers were available during the test, more test setups were performed, considering one sensor, indicated as n. 7 in Fig. 6, as reference transducer which was kept at the same location in all the setups. In each setup the accelerations were acquired in the presence of environmental actions (wind, passage of persons) [25] for a duration of 15 minutes at a frequency of 1024 Hz.

The environmental records carried out at the points of measurement have been inspected and validated. Subsequently, each recording was filtered by the application of a Butterworth-type bandwidth filter of order 6 in the range 0.2-20 Hz. Subsequently, the time series were decimated to obtain a final sampling frequency of 20 Hz. It is worth to note that filtering performed before decimation ensures the absence of aliasing problems in the frequency range of interest.

The data processing and the extraction of modal shapes were carried out with the commercial program ARTEMIS [26] both in the frequency and time domain to obtain the natural frequencies, damping ratios and modal shapes of different modes of vibration of the structure. In particular the Enhanced Frequency Domain Decomposition (EFDD) [27] and the data driven Stochastic Subspace Identification (SSI) [28] were used as output-only techniques.

The analysis of the data and the comparison of the results provided by the various methods allowed the identification of the fundamental modes of the structure and the validation of the data obtained. Specifically, the comparison of the estimates provided by the different methods (EFDD, SSI) showed a maximum frequency deviation of 0.6 % and CROSS-MAC values not less than 0.87 for all identified modal shapes.

Fig. 7 shows the modal shapes and values of natural frequencies and damping ratios for each of the identified modes. The latter can be classified as follows:

1. Transversal bending mode;
2. Vertical bending mode;
3. Vertical torsional mode.

In addition, the identified modes are all normal modes, as can be seen from the examination of the complexity plots shown in Fig. 8. It is hardly necessary to point out that the imaginary components present in some modes are minimal, clearly attributable to the effects of the measuring noise.

Figure 7: Experimental mode shapes.

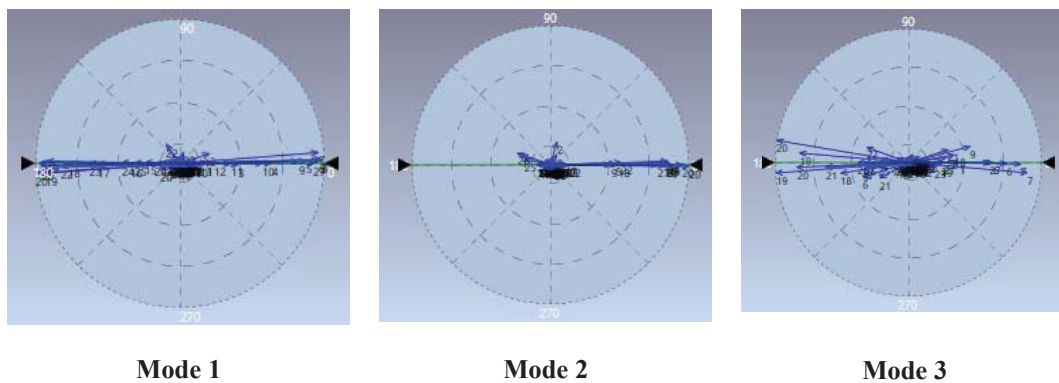

Figure 8: Complexity plots of the experimental mode shapes.

## 5 THE NUMERICAL MODEL OF BRIDGE

The FE model of the bridge assumed as case study was developed by the software SAP2000 [29]. The various components of the structure were modeled considering their real geometry with mono-dimensional (frame) and bi-dimensional (shell) finite elements, getting a three-dimensional model including deck and piers restrained at the base by hinges.

The concrete section was considered entirely reactive assuming prestressing effect efficient. The deck was modeled by thin "shell" elements, with 4 nodes and a formulation that combines membrane and plate-bending behavior. Stress and strain are evaluated in the local coordinate system of the elements in 2x2 Gaussian integration points and are extrapolated in the connection nodes between the elements. The nodes of discretization of the deck are approximately 4600 with a mesh of 1 x 0.7 m for the upper slab.

The piers were modeled using frame elements for the 8 pillars and shell elements for the transverse elements at the top and the bottom. Moreover, tendon elements were added in the model to simulate the presence of prestressed cables. Tendon elements are an object type that can be inserted into other objects (Frame, Shell, Plane, Asolid, and Solid) to simulate the effects of pre-stressing but in this dynamic analysis their effect is the stiffness and mass contribution.

**Errore. L'origine riferimento non è stata trovata.** 9 shows the view of the model implemented by the software SAP2000 [29].

The elastic modulus of concrete was evaluated by the Eurocode 2 formulation [30] using the mean concrete strength measured by the in situ tests, and resulted of 34700 MPa and 32700 for the concrete of piers and deck respectively. Furthermore a value of 196500 MPa from literature was adopted for the steel cables.

Figure 9: a) FEM model of the bridge including prestressed cables; b) extruded view of the model.

Fig 10 shows the deformed shapes of the first nine numerical modes that involve always the deck structure of the bridge and the piers for the modes that have horizontal components.

Mode I (f= 1.06 Hz)	Mode II (f=1.09 Hz)	Mode III (f=1.21 Hz)
Mode IV (f=1.74 Hz)	Mode V (f=2.14 Hz)	Mode VI (f=3.66 Hz)
Mode VII (f=4.36 Hz)	Mode VIII (f=4.45 Hz)	Mode IX (f= 4.71 Hz)

Figure 10: Numerical mode shapes of the bridge.

## 6. FIRST RESULTS OF THE STRUCTURAL IDENTIFICATION

Once the model was specialized on the basis of the in site detected geometry and the collected values of material mass and stiffness, a first comparison between the numerical and experimental results was carried out in terms of frequencies and mode shapes. The consistency of

the latter comparison was measured with the MAC index - Modal Assurance Criterion - which provides a measure of the degree of linearity between the vectors of the mode shapes [31]. A MAC index value close to unity indicate a high level of correspondence between the compared mode shapes. The results are reported in Table 1. The numerical model provides, among the first nine mode shapes, the experimental mode shapes identified with the dynamic test. In particular, the experimental modes correspond respectively to the fourth, fifth and ninth numerical ones as can be observed in Fig. 10.

Table 1. Theoretical-experimental comparison

Experimental		Numerical		
Mode N.	$f_{exp}$ [Hz]	Mode N.	$f_{FEM}$ [Hz]	MAC
1	1.18	1	1.19	0.86
2	2.12	5	2.12	0.98
3	5.69	9	4.72	0.76

As can be noted from Table 1 the assessment between numerical and experimental returns, with reference to the fundamental modes of the structure, a good agreement in terms of frequency and MAC for the two first experimental modes. Otherwise mode 3 shows a slightly lower correlation between the experimental mode shape and the corresponding numerical data, with a low MAC index of 0.76.

It is worth to note that the numerical model provides many in-plane and out of-plane bending modes of the deck that have not been detected by the dynamic test. Thus, the model needs to be calibrated to identify the actual conditions of the bridge, especially in terms of constraints, that avoid or reduce the movement of the bridge in the deck plane. Therefore, in the paper a first manually updating of the model was performed changing the following prominent items in agreement with physical phenomena due to real conditions observed during the investigation:

1) A fixed support was assigned to the base of the piers in the transverse direction (short dimension of the deck) because the hinge at the base of the pier may not be activated in the transverse direction for the environmental vibrations due to friction between the concrete of the pier and the foundation.

2) Fixed supports in transversal and longitudinal direction were inserted at the edges of the cantilevered spans to take in account that the longitudinal and transverse displacements are prevented because the gap between the bridge and the road has been filled with cement.

3) elastic supports were adopted at the longitudinal edges in vertical direction to take into account that gap below the bridge is not enough to avoid the support effect of the gabions and reinforced soil. A first calibration of the restraints stiffness has been made but this aspect needs of further study.

4) A rectangular beam was arranged along the two longitudinal sides of the bridge to consider the stiffness effect along the transverse direction due to the sidewalk added in 1982 by a steel structure bolted to the bridge. equivalent to.

5) The elastic modulus of the concrete for the piers (24000 MPa) was reduced to take account of the degradation phenomena of concrete cover evidenced during the in-situ survey. The above considerations, properly introduced in the numerical model modified the mode shapes of the model, and led to the correspondence of the order between experimental and numerical modes. In Table 2 the comparison of numerical and experimental modes after the updating is shown. An improvement of the correspondence between numeric and experimental behavior is also confirmed by the increment of MAC, after the first manual updating

of the model, that was necessary to introduce the correct boundary conditions that correspond to real circumstances and not to numerical optimization. Clearly a further step is necessary in the updating process in order to reduce the difference in frequency between experimental and numerical modes by a better assessment of the parameters values as the elastic modulus of the materials, the restraints conditions and the elasticity of the constraints.

Table 2. Theoretical-experimental comparison after updating

Experimental		Numerical		
Mode N.	$f_{\text{exp}}$ [Hz]	Mode N.	$f_{\text{FEM}}$ [Hz]	MAC
1	1.18	1	1.91	0.97
2	2.12	2	2.16	0.97
3	5.69	3	4.16	0.80

## 6 CONCLUSIONS

The study presents the complete procedure of structural identification of an existing bridge and the first results of the consequent model updating. The selected case study, that is a complex, even if not large, structure designed by Riccardo Morandi in '50 years, evidenced the following general aspects:

- The AVT is a suitable procedure to define the experimental behavior of a structure in the linear field because it doesn't require the time and organization for application of actions; however a reliable numerical elaboration of the results is necessary with more than a technique. A few number of sensors can be used applying more than one setup and combining the results by a suitable technique. In the case study 5 sensors were available but 8 setup allowed to have experimental results of 30 points along the bridge.
- The numerical model has to be developed considering the aspects that is necessary to update by the identification process. The basic model has to be developed considering the results of a detailed in situ investigation on geometry, materials and boundary conditions of the structure.
- A first updating process addressed by physical considerations of the conditions that can bring the numerical model near to the experimental behavior is important to avoid that a numerical optimization process can use other properties to attain the final results. In the case proposed herein some constraints are due to real in situ conditions (filling of the gaps between the road and the bridge not considered in the design) that influence the linear elastic response, therefore their presence have to be introduced before starting an update process of the elastic properties of the construction.

The strategy of carrying out a dynamic experimental test to calibrate a reliable model provides a good structural identification, allowing to accurately identify the real boundary conditions of the structure, not always possible without in situ tests. The presented work is in progress to complete the model updating and compare the behavior of the structure evidenced by the dynamic test with the one obtained by a load in situ test.

### Abstract

*This paper presents the experimental test campaign to calibrate a finite element model intended to evaluate the seismic vulnerability of the SS Filippo e Giacomo historical masonry arch bridge in Ascoli Piceno (Italy).*

*The bridge was built in 14<sup>th</sup> century and had undergone very complex vicissitudes related mainly to exceptional floods; it was partially rebuilt twice and other strengthening works were carried out over the time. The bridge, which is almost completely built with travertine blocks, has a total length of 146 m and follows a slightly curved path. Six arches, the main of which is semi-circular with span of 25 m and the others are lancet arches with span of about 8 m, support the carriageway that is about 8 m wide. The piers and abutments are founded on the bedrock and consequently some piers are deeply embedded in the sandy gravel deposit.*

*A campaign of experimental tests was executed encompassing onsite measurements of stresses and modulus of elasticity as well as laboratory measurements on specimens taken from the structures. Vibration tests were also carried out to evaluate the modal properties of the bridge. The acquired experimental data were used to calibrate a 3D model that has been developed also including the soil deposit. A very good consistency was achieved between experimental and theoretical behaviors.*

## 1 INTRODUCTION

Evaluation of a historical masonry structure is a difficult task because of many uncertainties associated with the knowledge of the structure in its current conditions (original structure and structural changes due to repair enlargement and retrofit works, different construction systems and different materials, structural and material degradation and damages, soil and foundation modifications) and also due to modelling techniques complexity as well as to analysis methods. In this sense, after a deep historical analysis and a complete geometrical and structural survey, sophisticated measurement techniques are necessary to catch the real behaviour of the structure, especially the mechanical properties of the structural materials and the global dynamic behaviour.

About the material survey, both traditional techniques and innovative methods are available but non destructive techniques are generally preferred when dealing with historic and valuable structures. An extensive test campaign on material may permit to fix a large part of the most important parameters in the definition of the structural finite element model. The global dynamic behaviour of the structure can be experimentally determined by means of several kinds of test such as forced, impulse, release or ambient vibration tests, by using modal identification methods [1], [2], [3]. In the last decades ambient vibration test, with the relevant output-only modal identification methods, has become the preferred test typology for evaluating the modal parameters of full scale structures and especially for historic structures since no artificial excitation is required and the test can be carried out in operational conditions without interrupting the use of the structure and causing a minimum interference with it [4]. The experimental modal parameters can then be used to update refined finite element models able to describe the real behaviour of structures, which can be required for structural verifications and for designing repair and retrofit works [5], [6], [7].

This paper presents the experimental test campaign and the finite element model updating of the SS. Filippo and Giacomo Bridge over the Tronto river at Ascoli Piceno, in the centre of Italy. The bridge was built in the XIV century and was then subjected to many changes for repair, strengthening, retrofit, and enlargement works. This results in a large complexity of the structural organism, due to interaction between parts of different age which are made of materials with different mechanical properties. Due to these uncertainties and considering the importance of the bridge an accurate analysis of its current conditions was deemed essential to obtain a reliable predictive finite element model to be used for the design of seismic retrofit. First of all a historic study and geometric survey of the bridge were developed. For the material properties in-situ tests, both destructive and non destructive, were carried out, to evaluate the quality of the travertine block masonry. These information were used to develop a refined 3D finite element model that was tuned based on the experimental modal parameters; in particular, the Young's modulus of some materials initially defined according to standard values suggested by codes, was calibrated to fit the dynamic behaviour obtained experimentally.

## 2 “SS. FILIPPO AND GIACOMO” BRIDGE

“SS. Filippo and Giacomo” Bridge rises in a less urbanized area of Ascoli Piceno town and crosses the Tronto River in a short straight section comprised between two loops. It was partially rebuilt twice and other strengthening works were carried out over the time.

It has a total length of 146 m and maximum height over 20 m. The bridge is built between two rock escarpments; one of which is characterized by an important slope (Figure 1).

Six arches constitute the bridge. The main arch crosses the river during its regular flow and has a semicircular shape with span of about 25 m. The arch barrel has the minimum thickness of 0.90 m at the crown and increases up to 1.40 m at the imposts.

Figure 1: Aerial photogrammetric bridge view.

The other five arches are lancet shaped with span of about 8 m. The depth of the fill at the crowns of arches is variable from about 6.0 to 7.5 m. The spandrel walls have thickness of about 1.0 m. All the piers are placed at the right bank occupied by the river during exceptional floods. The plan path is mostly rectilinear with a bend in proximity of the left abutment.

The two-lane road is almost 6 m wide and is flanked by two about 1 m wide sidewalks that were realized in the first half of the 20th century by enlarging the bridge with a double series of pensile semicircular small arches, with spans of about 4 m, sustained by stone corbels.

The bridge, is completely built with travertine blocks with exception of the twentieth-century pensile arches and of inner lightening rooms that are realized with brick masonry.

## 2.1 Geometrical, material and geological survey

The range-based survey used to acquire geometrical/metric data was made by means of a 3D-TOF laser scanner technique. Both the external geometry and the geometry of the various internal vaulted rooms over the main arch, at the pier top and at the abutments, were surveyed. Wooden and steel ties, placed to avoid the spandrel wall overturning toward outside were also surveyed in the accessible zones. The acquired dataset was then processed to obtain a refined 3D geometrical model that was later used to generate a structural model with very precise geometry and rigorous mass distributions. Such a kind of survey revealed to be extremely useful in the case under consideration characterized by a very complex geometry.

Piers is characterized by an external curtain, having variable thickness and realized with Ascoli Piceno travertine squared blocks, and an important internal, rather irregular, rubble stone infill characterized by the presence of water in the lower parts. For what concerns the masonry of the interior vaulted rooms, it was built with a good quality brick masonry. Nevertheless, it is worth noticing that such components are not expected to give a significant contribution to the overall behavior of the structure excepting for the mass.

The bridge rises between two rock escarpments produced by erosion of Tronto River (Figure 2). The left escarpment has a rather high slope ( $52^\circ$ ) whereas the right one is less sloping ( $31^\circ$ ). The gorge is characterized by a sandy gravel deposit on the right riverbank, with variable thickness up to 10 m, whereas the sandstone bedrock is outcropping at the left riverbank. Investigations carried out in correspondence of piers P1, P2 and P3 demonstrated that foundations are placed at the sandstone bedrock which is horizontal; despite other specific analyses were not carried out for the other piers (P4 and P5) there is no evidence (e.g. vertical settlements) that these are founded over the deposit; the sandy gravel deposit is thus placed around the pier but not under the foundation layer.

Figure 2: Geological configuration and foundation level.

### 3 OPERATIONAL MODAL TESTING

#### 3.1 Instrumentation and tests

The modal parameters of the bridge, i.e. natural frequencies, damping ratios and mode shapes, are experimentally estimated by means of operational modal analysis starting from the accelerations of the deck recorded during ambient vibration measurements which are mainly due to traffic, wind and microtremors. The tests are performed by using 8 low noise piezoelectric uniaxial accelerometers, a 24-bit data acquisition system, and coaxial cables (Figure 3). Different configurations are adopted in order to identify the global behaviour of the bridge; in this paper only that useful to investigate the transversal behaviour is reported and analysed.

Two configurations were considered in order to capture transversal and vertical-torsional behavior of the bridge (Figure 4). In order to capture the transversal behavior, 8 accelerometers aligned throughout the longitudinal axis of the bridge and oriented in transverse direction were installed (Configuration 1), while to capture the flexural-torsional response, 8 accelerometers lined up in pairs and oriented in vertical direction were installed (Configuration 2).

Time histories 1000 seconds long, sampled at a rate of 2048 Hz (the minimum sampling rate for the used data acquisition system), were acquired. This time length provides enough data to obtain modal parameters with a good accuracy, as reported in [8] where an acquisition time longer than about 1000-2000 times the fundamental period, is recommended (in this case a value of about 2.5 Hz was obtained from preliminary measurements that leads to 400-800 s).

Before performing the operational modal analysis all the recorded data were processed by means of suitable signal processing techniques: trend removal, low-pass filtering (to eliminate the contribution of high frequencies and to avoid aliasing phenomena) and down-sampling at 51.2 Hz, in order to decrease the amount of data and make faster the successive analyses.

Figure 3. Instrumentation and uniaxial accelerometers.

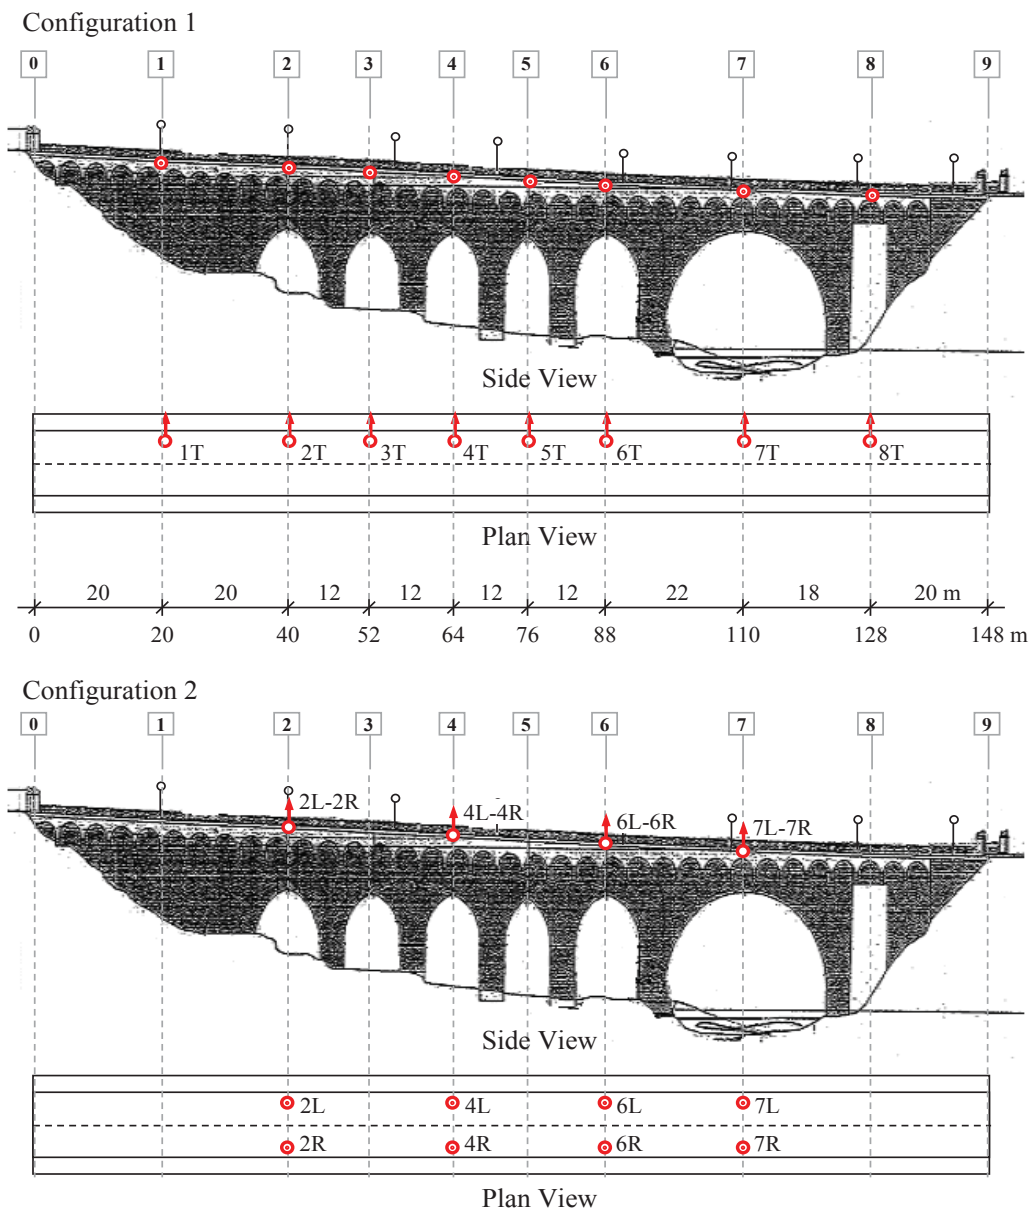

Figure 4. Location of accelerometers for the two configurations

### 3.2 Operational modal analysis (methods and results)

The Covariance-Driven Stochastic Subspace Identification (SSI-Cov) is used to estimate the modal parameters on the basis of the accelerations recorded during the ambient vibration test. This method uses a stochastic state-space model, simplifying the second-order system of differential equation that describes the dynamic problem into a first-order system. Starting from the recorded data sampled at discrete interval, the stochastic state-space model is represented by [9]

$$\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k + \mathbf{w}_k \quad (1)$$

$$\mathbf{y}_k = \mathbf{C}\mathbf{x}_k + \mathbf{v}_k \quad (2)$$

where  $\mathbf{x}_k$  is the discrete-time state vector at time instant  $k$ ,  $\mathbf{y}_k$  is the vector of the output,  $\mathbf{A}$  is the discrete state matrix,  $\mathbf{C}$  is the discrete output matrix, and  $\mathbf{w}_k$  and  $\mathbf{v}_k$  represent the process and measurement noise respectively. The Toeplitz matrix containing the covariance matrices of measured accelerations is used to extract  $\mathbf{A}$  and  $\mathbf{C}$  matrices by means of a Singular Value Decomposition and a least square procedure [10]. The modal parameters are obtained by the two matrices characterizing the state-space model. The SSI-Cov permits the estimation of a number of modes depending on the model order used in the state-space model. The physical modes are separated by the spurious ones by means of the stabilization diagram which allows the identification of (y-axis) the stable modes (x-axis) i.e. the modes presenting modal parameters (natural frequencies, damping ratios and mode shapes) which remain similar as the model order increases (Figure 5). In this work models with up to 40 order are used and the modes are considered to be consistent if, when increasing the model order one by one: (i) natural frequency variation is less than 1%, (ii) damping ratio variation is less than 2%, and (iii) Modal Assurance Criterion (MAC) between the modes is greater than 98%.

Table 2 reports the natural frequencies with the relevant damping ratios obtained with the operational modal analysis in the frequency range 2-6 Hz from Configuration 1, while Figure 6 shows the normalized modal shapes obtained with SSI-Cov method. The modes identified are the transversal modes typical for such a masonry bridge. The modal parameters estimated experimentally are crucial to evaluate the reliability of the model and to calibrate some important parameters. Table 3 reports the natural frequencies with the relevant damping ratios obtained with the operational modal analysis from Configuration 2, while Figure 7 shows the normalized modal shapes obtained with SSI-Cov method.

In this case the natural frequencies and mode shapes estimated in Configuration 1 are used in the sequel to calibrate the mass distribution along the bridge length (based on some assumption in absence of experimental survey) and the elastic modulus of the travertine masonry.

## 4 STRUCTURAL MODEL OF THE BRIDGE

### 4.1 Finite element model

Model for the overall structural analysis is developed in Straus7 [11] by integrating data available from the laser scanner survey. In particular, the 3D model (Figure 8a) encompasses a suitable portion of the soil deposit with variable depth in order to account for the particular geological configuration and to capture effects of soil-pier interaction.

The finite element model is obtained with a mesh of 4-node tetrahedral elements with linear interpolation shape functions (Tetra4). The mesh is generated by importing a closed poly-surface constructed by approximating the geometry obtained with the laser scanner survey.

For such a purpose the geometry is simplified in order to avoid excessive refinement of the mesh due to details that do not actually affect the overall behavior of the bridge; at the same time all internal rooms and the earth fill are modelled in order to capture the real stiffness and mass distribution of the structure. Maximum length imposed to the element edge is 1.0 m for the bridge structure whereas it is increased up to 4.5 m for the elements of the soil deposit (Figure 8b). Fixity restraint are placed at the deposit base and at the structure sections interacting with the sand stone formation. The model is constituted by 120,545 elements for a total of 75,204 degrees of freedom. All the materials, including earth fills and the soil deposit, are considered to be linear elastic and isotropic.

Figure 8. (a) Geometrical model; (b) Finite element model.

### 4.2 Model tuning

The mechanical parameters of the finite element model are calibrated by fitting the experimental modal parameters with numerical ones relevant to the finite element model previously discussed. Initial value of the parameters are selected according to the valued reported in the Italian standard [12-13].

Figure 9a shows the first four mode shapes obtained by means of model calibration changing only the elastic modulus of the travertine masonry constituting the main structure. In Figure 9b the comparison among the first four experimental and numerical mode shapes is reported, while Table 4 reports the percentage errors relevant to the frequencies and the approximation of the mode shapes by means of the MAC

$$MAC = 100 \times \frac{(\boldsymbol{\varphi}_i \cdot \tilde{\boldsymbol{\varphi}}_i)^2}{(\boldsymbol{\varphi}_i \cdot \boldsymbol{\varphi}_i)(\tilde{\boldsymbol{\varphi}}_i \cdot \tilde{\boldsymbol{\varphi}}_i)} \quad (3)$$

which tends to 100 when the theoretical  $(\boldsymbol{\varphi}_i)$  and experimental  $(\tilde{\boldsymbol{\varphi}}_i)$  modes tends to be equal.

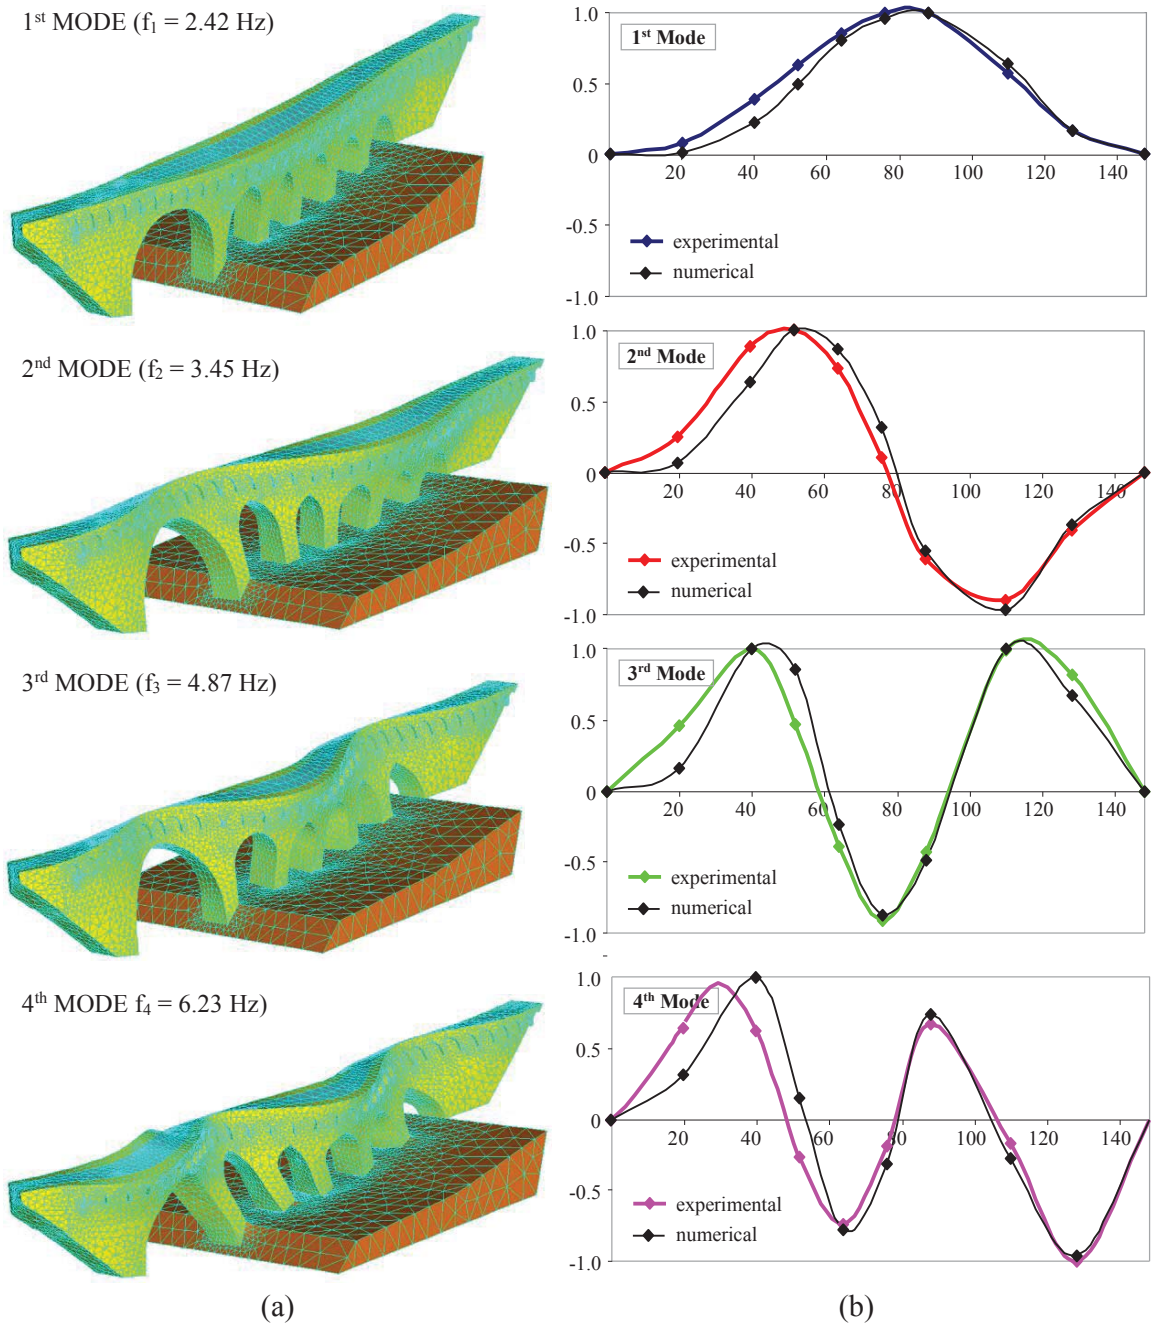

Figure 9. (a) First four transverse vibration modes; (b) Comparison between experimental and numerical modes

Mode	Frequency (Hz)		Error (%)	MAC (%)
	Experimental	Numerical		
1	2.46	2.42	1.55	98.58
2	3.30	3.45	-4.67	95.43
3	4.54	4.87	-7.34	93.37
4	5.61	6.23	-10.99	86.45

Table 4. Comparison between experimental and numerical results

The parameters used in the model are reported in Table 5. The soil parameters are derived from geotechnical tests while infill materials are hypothesized.

Material	E (N/mm <sup>2</sup> )	G (N/mm <sup>2</sup> )	w (kN/m <sup>3</sup> )
Travertine masonry	7000	2414	22
Brick masonry	1282	427	18
Earth fill	666	238	18
Soil deposit	666	243	19

Table 5. Mechanical parameters of materials

## 5 CONCLUSIONS

An experimental test campaign aimed at calibrating the finite element model of a historical masonry bridge, characterized by an unusual geometry deriving by very complex historical vicissitudes, has been presented. The bridge rises in a gorge and is founded on a sand-stone deposit that is outcropping at the abutments. The bridge is constituted by six different arches whose piers are founded on the sand-stone formation and are embedded for significant sections (up to 10 m) into the fluvial deposit constituted by sandy-gravel soil.

A laser scanner survey was crucial to obtain a model encompassing all main features of the real structure such as the inner lightening rooms, with very irregular geometry, as well as the pensile arches constructed to enlarge the carriageway.

The onsite tests permitted the evaluation of the main mechanical characteristics of the materials and the estimation of the stress state in critical sections of the piers.

The operational modal analysis, used to detect the dynamic behavior of the bridge, was decisive for tuning a finite element model capable of predicting the overall behavior of the bridge.

### Abstract

*This paper presents the results of the dynamic monitoring carried out on a school building in central Italy during the seismic sequence following the first main shock of the 2016 Central Italy earthquake. The building is located in the historical centre of Camerino and consists of a reinforced concrete frame structure with masonry infill walls. The school, dating back to the 60s, underwent seismic retrofit in 2013 through the construction of 2 dissipative towers, a recent patented system for seismic protection of buildings.*

*In August 2016 a dynamic monitoring system was installed on the building, positioning an array of accelerometers both on the top two floors of the structure and on the foundation level; this made it possible to record the building response to the aftershocks that occurred during the monitoring period, and the corresponding seismic input. The dynamic characteristics of the structure during the monitoring period are identified starting from the response of the structure subjected to the seismic swarm following the main event, and to the environmental vibrations between two subsequent events.*

*Although during the monitoring days the building did not suffer any damage, the response of the structure proved to be nonlinear and strongly dependent on the amplitude of the accelerations to which it was subjected; in this work, a procedure to linearize the structural response and carry out the dynamic identification in terms of modal parameters starting from the non-stationary response of the structure is proposed.*

## 1 INTRODUCTION

There has been a progressive increase in attention in recent years to the usefulness and advantages of permanent monitoring systems in the field of civil engineering. Recording the dynamic response of structures during seismic events can ensure significant benefits: on one hand, it provides useful information for damage detection and post-earthquake emergency management and, on the other hand, it can allow the improvement of the seismic risk assessment through the decrease of uncertainties relevant to both the hazard estimation and structural vulnerability. The reduction of uncertainties relevant to the structural vulnerability can derive from the validation of structural models based on the registration of the structural response subjected to low-medium intensity events while the reduction of uncertainties relevant to the hazard requires the monitoring of the soil-foundation system through which the validation of soil and source models can be attempted.

With respect to low-medium intensity earthquakes, an interesting aspect that emerges from the monitoring is the well-known variability of the dynamic properties of structures during shaking in absence of damage producing a "wandering" of the modal parameters of the construction that can be attributed to minor nonlinearities of the response [1] such as the light cracking of infills or frictions relevant to the interactions between structural and non-structural components. The latter issue, in addition to the well-known dependence of structural frequencies on the environmental conditions [2, 3, 4], makes the identification of structural damage from records obtained from continuous monitoring systems particularly problematic. In the literature it is possible to find several works that address the problem with reference to historical masonry buildings [5, 6, 7], but a limited number of works refer to reinforced concrete structures.

With the aim of providing a contribution in this research area, this paper presents an approach for tracking the fundamental frequencies of monitored buildings accounting for their nonlinear response, triggered by low-medium intensity earthquakes. The procedure is applied to a record extracted from the monitoring of a school building, the Liceo Varano located in Camerino in the province of Macerata (Italy), during the seismic swarm following the earthquake in central Italy in August 2016.

## 2 DESCRIPTION OF THE BUILDING

The building at hand dates back to the 60's and was born from the decision to enlarge and rehabilitate the old masonry building constituting the Liceo Ginnasio Napoleonico since 1833 and, before, the Convent of Santa Elisabetta. Part of the new building is founded on the old convent, while the other part rests on the ground. The building has an L-shaped plan formed by two wings, indicated in Fig. 1a and Fig. 1b with "A" and "B". The structure consists of reinforced concrete frames; beams have a rectangular section, excepting those on the perimeter, which are characterized by cross-sections with a tapered articulated geometry (i.e. with variable height and width) (Fig. 1c). All columns have a square cross-section rotated by  $45^\circ$  with respect to the direction of the frames for architectural reasons, with dimensions equal to 35x35 cm, excepting two inner columns of body "A" that have a 42x42 cm cross-section.

In 2013 the building was seismically retrofitted through the construction of two Dissipative Towers [8] (Fig. 1d), one connected both to body "A" and to body "B" (Tower A) and the other only to body "B" (Tower B). The towers rest on a thick reinforced concrete plate connected by a central spherical hinge to a second slab founded on piles. Simplifying as much as possible the description of the retrofit, it can be stated that the Towers have the twofold aim (i) to regularize the horizontal displacements of the building, favoring a linear deflection (i.e. constant inter-story drifts), and (ii) to increase the dissipation of the seismic input energy through viscous

dissipative devices that exploit the relative velocities between the two reinforced concrete plates at the base of each Tower.

During the seismic retrofit, dynamic ambient vibration tests were performed to identify the modal parameters of the building. A first dynamic identification was conducted in 2012, before the intervention, and a second one was carried out in 2013 upon completion of the upgrading work. The purpose of the investigations carried out was twofold: on one hand, the preliminary identification tests allowed to obtain information on the global dynamic behavior of the building to support the design of the intervention and the calibration of a finite element model; on the other hand, the investigations in the post-operam situation allowed to verify that the modal parameters of the retrofitted structure matched those predicted by the numerical model. More details on the intervention, which is heavily constrained by technical requirements, can be found in Balducci et al. (2015) [9], while a more extensive description of the tests and the relevant results can be found in Gara et al. (2021) [10].

### 3 DESCRIPTION OF THE DYNAMIC MONITORING

After the seismic event of magnitude 6.0 occurred on August 24, 2016, a new ambient vibration test was performed on August 27, 2016, with the purpose of verifying the health of the structure. Fig. 2a shows the sensor configuration adopted for each floor of the building while Fig. 2b shows a photo of the acquisition system. As for the instrumentation, PCB 393B31 piezoelectric sensors with a sensitivity of 10 V/g, NI 9234 analog-to-digital conversion boards with a resolution of 24 bits, a cDAQ 9178 chassis, and a notebook for data acquisition and

storage have been used. A sampling rate of 2048 Hz has been used for the acquisitions. Fig. 2c shows the frequency content of the recordings carried out while Fig. 2d and Fig. 2e show the results of the dynamic identification performed using the SSI-COV algorithm and the MAC (Modal Assurance Criterion) matrix. It is worth to specify that the building dynamics after the event of August 2016 remained unchanged from that identified after the retrofitting in 2013.

Following this test, a continuous dynamic monitoring system has been installed on the structure for three days; the system was composed by the same instrumentation adopted to perform the benchmark tests but additional accelerometers were installed at the foundation level in order to record the seismic input. Ambient vibration tests at the beginning of the monitoring allowed the identification of modal parameters that were subsequently traced via the continuous monitoring system. During the monitoring days (from August 27 to 29, 2017) several earthquakes occurred; the event with the highest intensity of magnitude 4.2 was registered on August 28 and occurred approximately 37 km away from the building.

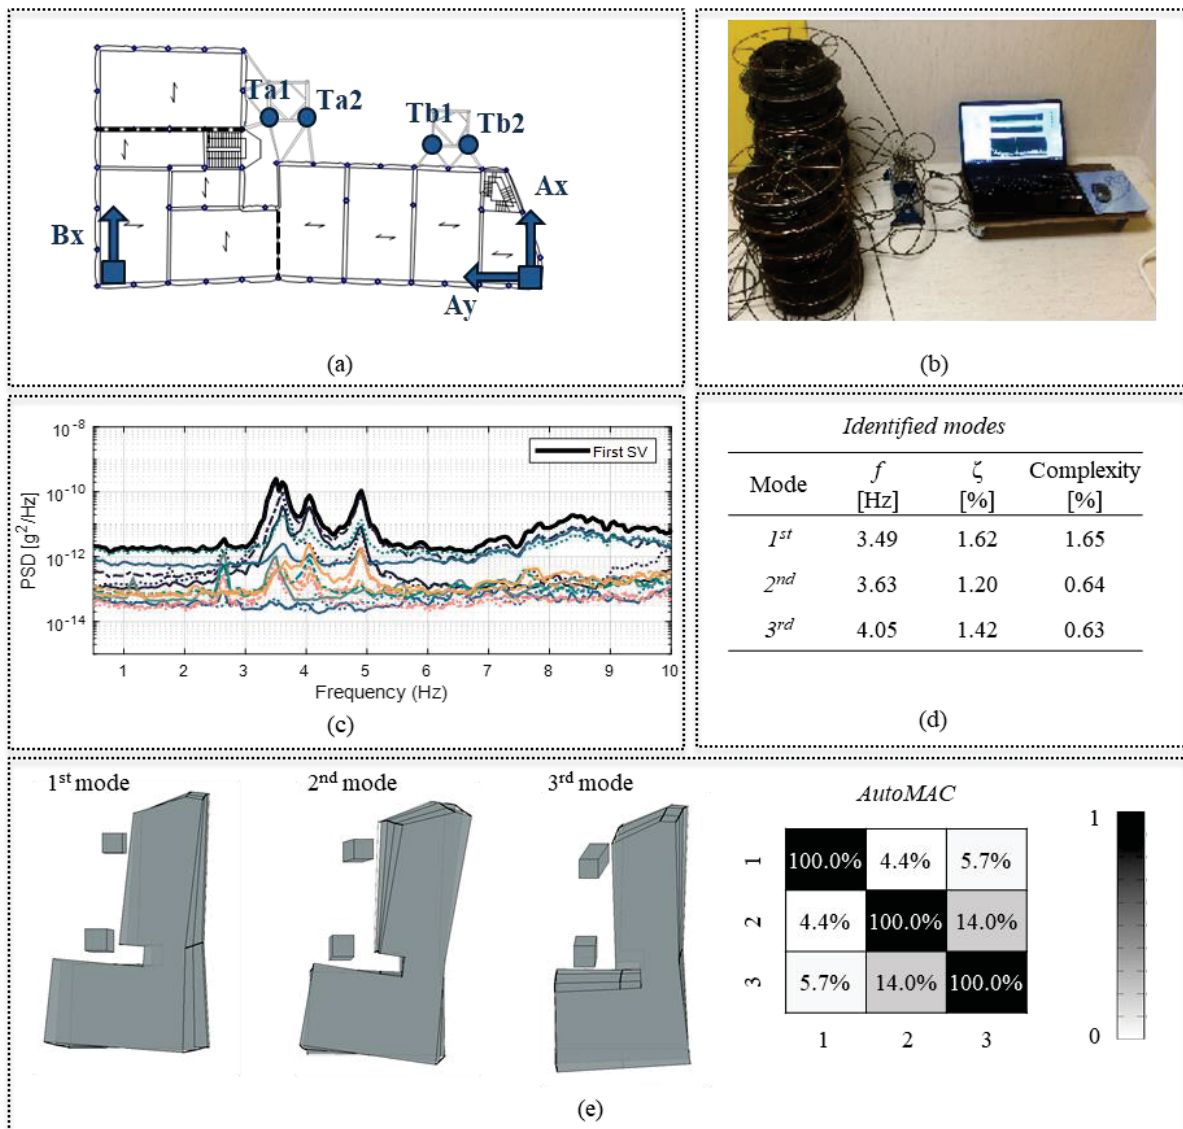

Figure 2: a) Sensors configuration adopted for each floor; b) acquisition system; c) frequency content from measurements during ambient vibration test; d) results of the dynamic identification; e) identified modal shapes and relevant AutoMAC matrix.

#### 4 DESCRIPTION OF THE LINEARIZATION PROCEDURE

For all the registered events, the structure exhibited a nonlinear response that made it difficult to identify its modal parameters from the seismic response. Fig. 3 shows a time-frequency analysis, performed using the Short Time Fourier Transform (STFT), performed on the measurement of the magnitude 4.2 event for the sensor on the top floor (location Ay). From Fig. 3, it is possible to observe the non-stationarity of the structural response, which leads the need of implementing a method to linearize the structural response.

Figure 3: Short Time Fourier Transform carried out on a record made during the magnitude 4.2 event.

The proposed algorithm takes advantage of the subspace identification methods; the latter are well established in the civil engineering field and are considered as robust and reliable algorithms. The recurrent algorithms in the literature, for the identification of MIMO systems are the Multivariable Output Error State Space (MOESP) [11] and the numerical algorithm for Subspace State Space System IDentification (N4SID) [12]. Many works can be found in which above algorithms have been successfully used for dynamic identification of full-scale case studies during seismic events [13, 14, 15, 16]. The first step in using the subspace identification algorithms is to write the dynamical system in the state space, through a state equation (Eq. 1) and an output equation (Eq. 2):

$$\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k + \mathbf{B}\mathbf{u}_k + \mathbf{w}_k \quad (1)$$

$$\mathbf{y}_k = \mathbf{C}\mathbf{x}_k + \mathbf{D}\mathbf{u}_k + \mathbf{v}_k \quad (2)$$

where  $\mathbf{u}_k \in \mathbb{R}^m$  and  $\mathbf{y}_k \in \mathbb{R}^l$  denote the input and output signals, respectively, at a certain time  $k$ , while  $\mathbf{x}_k \in \mathbb{R}^n$  is the state vector. In addition,  $\mathbf{A} \in \mathbb{R}^{n \times n}$  is the dynamical system matrix,  $\mathbf{B} \in \mathbb{R}^{n \times m}$  is the input matrix that describes how the deterministic inputs influence the next state,  $\mathbf{C} \in \mathbb{R}^{l \times n}$  is the output matrix that characterizes how the internal state influences the outputs and  $\mathbf{D} \in \mathbb{R}^{l \times m}$  is the direct transition matrix. For a linear time-invariant system above matrices are constant. Furthermore,  $\mathbf{w}_k \in \mathbb{R}^n$  and  $\mathbf{v}_k \in \mathbb{R}^l$  are unmeasurable vector signals, which are assumed to be normally distributed, zero mean, white noise signals.

For the case study under investigation, the structural response to seismic events of the building at hand is clearly time-varying, and it can therefore be assumed that the system matrices of the state space model change with time  $k$ . Several works in the literature deal with methods for

the identification of time-varying systems; in particular, some interesting algorithms are the MOESP-VAR [17], the N4SID-VAR [18], and the one proposed in Loh and Chen [19].

In this paper, an iterative procedure for the identification of the time-varying dynamical system is proposed, based on the optimization of the number of samples, and thus the length of the signal windows, in which the dynamics of the system can be described as a linear time-invariant process. The length of the first window is selected from the results of the time-frequency analysis and varied until the identified dynamic model accurately reproduces the experimental response starting from the measured input. The steps of the optimization procedure are summarized in the flowchart of Fig. 4; the identification within each window was done through the "robust combined algorithm" proposed by Van Overschee and De Moor in [12]. The accuracy of the identified model in reproducing the building response is evaluated comparing the predicted and measured time histories of accelerations through the comparison metrics proposed by Kavrakov et al. [20], which consider several signal properties such as phase, peak, root mean square, and frequency contents. A detailed explanation of the approach can be found in Gara et al. (2021) [21].

Fig. 5 shows the results obtained by applying the proposed procedure on the seismic response of the building to the magnitude 4.4 event. In particular, Fig. 5a shows the comparison between the signal recorded at the measurement point Ay at the top floor and the response estimated by the identified time-varying dynamical system. Figs. 5b and 5c show the results in terms of modal parameters (resonant frequencies and damping ratios) and reveal how the first three frequencies of the structure decrease during the strong motion and then gradually come back to the initial values at the end of the event; an opposite trend is observed for the damping ratios. The explanation is probably to be sought in the nonlinear phenomena, e.g. light infill cracking, frictions, and interaction phenomena between structural and non-structural members that are triggered above a certain level of excitation provided to the structure.

## 5 CONCLUSIONS

An approach for tracking the fundamental frequencies of monitored buildings accounting for their nonlinear response triggered by low-medium intensity earthquakes has been presented in this paper. The procedure, consisting of an iterative algorithm aimed at identifying signal windows in which the dynamics of the system can be described as a linear time-invariant process, is applied to a record extracted from the monitoring of a school building located in Camerino during the seismic swarm that followed the August 2016 Central Italy earthquake. The results highlighted the nonlinearity of the building seismic response even in the absence of damage, providing a useful tool for the interpretation of accelerometric data in structural health monitoring.

### Abstract

*Portico Varano in the Ducal Palace of Camerino (Italy) is a Renaissance monumental quadriporticus that was severely damaged by the Central Italy earthquakes in 2016. Within the field activities for saving cultural heritage foreseen within a recent European research project, a long-term static and dynamic monitoring system was installed in October 2020. Through a series of accelerometers, the monitoring system allows to track the evolution of the modal parameters of the structure, namely frequency, damping ratio and modal shapes, and investigate the effects of environmental conditions on the building dynamics. Furthermore, a series of displacement transducers installed on the vaults of the courtyard allows controlling the evolution of the crack patterns. In this paper, the design and installation of the monitoring system as well as some first results are presented and discussed.*

## 1 INTRODUCTION

The Italian architectural heritage is constituted by a wide number of historical masonry constructions such as churches, towers, buildings, and fortresses, characterized by both structural and typological vulnerabilities, which are often responsible for their poor seismic performance, e.g. [1-3]. Such situation is unfortunately periodically confirmed by the damage observed after the occurrence of seismic events, inevitable reminders of the high seismic risk of the Italian peninsula.

The analysis of the seismic vulnerability of architectural heritage requires an integrated approach where different disciplines provide indispensable contributions: historic investigations of the construction evolution; survey of the construction; in situ experimental testing and characterization of the materials; structural modelling and seismic analysis. Such contributions do not necessarily have a predetermined chronological sequence, given that the results of one of them influence the development of the investigations of the other three [4]. Among the various possibilities for experimental testing, dynamic testing under service conditions, commonly referred as Operational Modal Analysis (OMA), e.g. [5], constitute a very effective tool for structural identification and model updating, essential tools to support model-based simulation for the prediction of the seismic response of heritage constructions as well as for the calibrations of advanced seismic upgrading interventions, e.g. [6]. Examples of recent structural monitoring studies in the Italian architectural heritage include: the Consoli Palace in Gubbio [7], the church of Santa Maria in Collemaggio in L'Aquila [8], the San Pietro bell-tower in Perugia [9], the Milan Cathedral [10], the San Vittore bell-tower in Arcisate [11], and the Rubbianello Bridge [12].

This paper adds to the above list and presents the first results from a structural monitoring system installed in the quadriporticus of the Ducal Palace in Camerino, within the field activities planned in the European research project named ARCH (Advancing resilience of historic areas against climate-related and other hazards - <https://savingculturalheritage.eu/>) funded in the Horizon 2020 framework for the years 2019-2022. The objective of the ARCH project is the evaluation of the resilience of the historical centres and the risk management related to climate change and other natural disasters.

## 2 THE DUCAL PALACE IN CAMERINO

The Ducal Palace (Figure 1) is one of the main Renaissance monuments of the city of Camerino, located in Central Italy in the inner Apennine area of the Marche Region, about 65 km from the Adriatic Coast, 70 km from the city of Perugia and 190 km from Rome. The building hosted the headquarters of the University of Camerino before the 2016 Central Italy seismic events. The nucleus has ancient origins, remodelled at the end of the XIV century and completed in the second half of the XV century under Giulio Cesare da Varano. Over the centuries, the layout of the Palace underwent many modifications thanks to acquisitions that led to the incorporation of other surrounding buildings. These caused a continuous structural reorganization and maintenance works, resulting in a very complex and densely stratified palace. Continuous interactions between the building and the city led to architecture and urban spaces that were mutually conditioned. For this reason, the Ducal Palace is also defined as “part of the city”.

The quadriporticus courtyard (Figure 1a,e), also called Portico Varano or Sottocorte, probably designed by the great military architect Baccio Pontelli, is the central architectural element around which the palace is organized. Before the damages following the 2016 Central Italy earthquakes, the quadriporticus courtyard played a key role in the social life of the academic community of the University of Camerino.

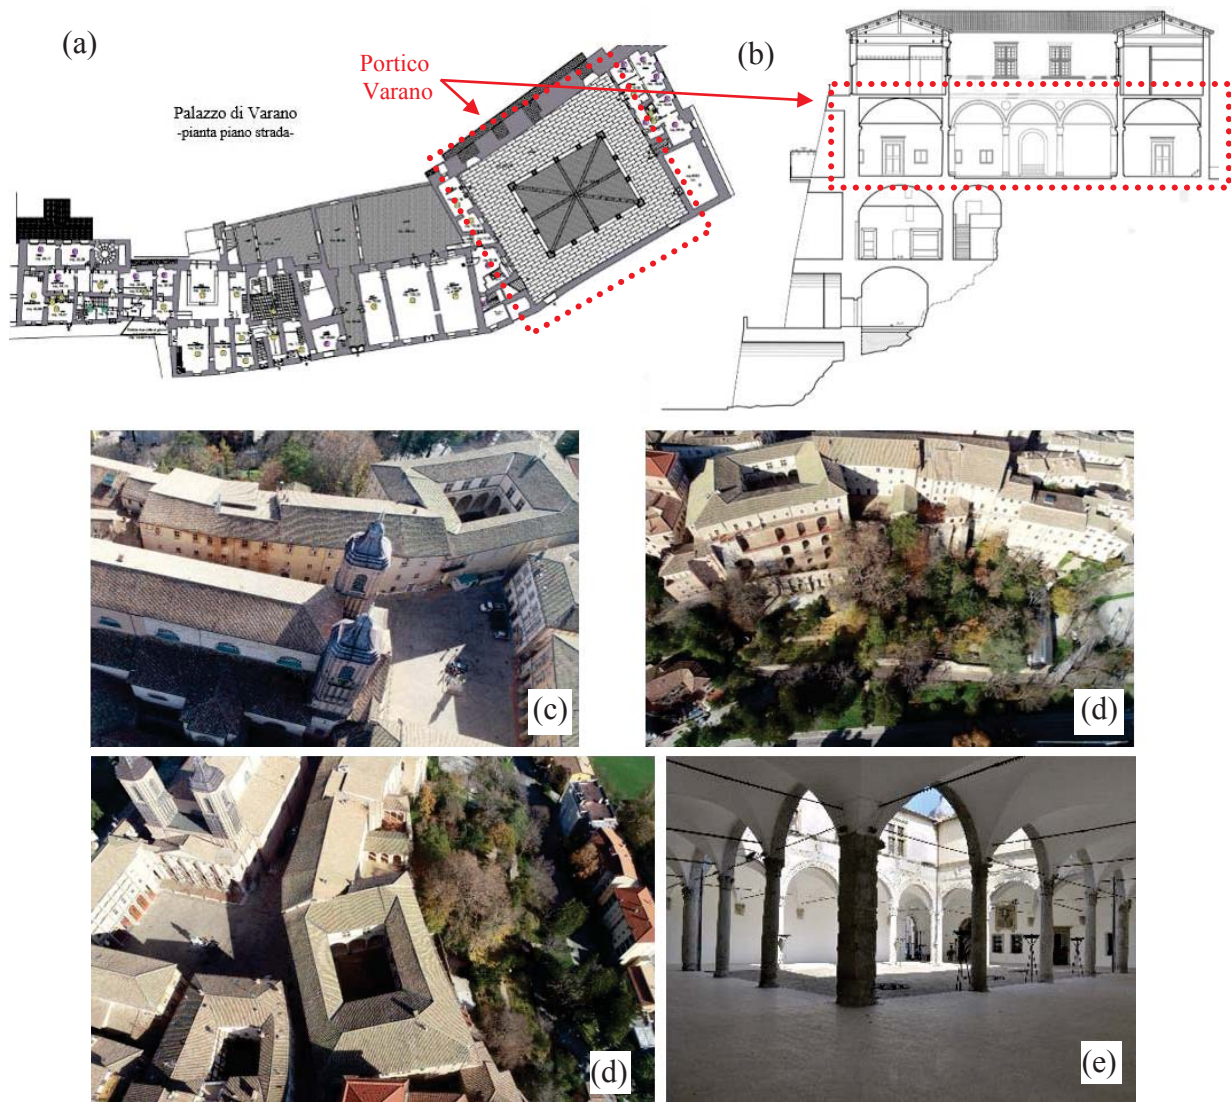

Figure 1: Ducal Palace Camerino, Italy (a) layout at the street level; (b) vertical section; (c) aerial view from the North-West side (d) aerial view from South-East; (d) aerial view from South-West; (e) view of the inner courtyard from the North corner of the quadriporticus.

After the latest seismic sequence that hit central Italy from August 2016 to January 2017, the structural vulnerabilities of the Ducal Palace were exposed, with damage observed both in the elevation structures and in the floors (for example some sample photos are shown in Figure 2). Damages in the vault of the quadriporticus, and in the perimeter walls interdicted the public access to the Ducal Palace and required safety measures (Figure 2). In addition, important damages concerned non-structural element with detachment of internal plaster and cracks in the “camorcanna” ceilings, some of them decorated with fresco paintings.

Figure 2: Examples of the damages in “Portico Varano” after the 2016 Central Italy earthquakes.

### 3 MONITORING SYSTEM AND FIRST RESULTS

#### 3.1 Preliminary monitoring system and dynamic characterization

The Ducal Palace is a very complex case study and reliable structural models were not available in the first stage of the field activities foreseen in the ARCH project. For this reason, preliminary structural monitoring tests were made in June 2020 in order to provide a characterization of the dynamic behaviour of the quadriporticus under ambient-induced vibrations to support the first evaluations on its structural behaviour.

The instrumentation adopted during this preliminary experimental campaign consisted of 12 uniaxial high sensitivity piezoelectric accelerometers (PCB model 393B31) connected through high-quality shielded coaxial cables to the acquisition system (National Instruments cDAQ-9178 installed with NI 9234 analogue-to-digital converters) controlled through a Dell Precision 7540 laptop running National Instruments Signal Express software. The accelerometers were placed on the first floor as depicted in Figure 3 in order to provide a comprehensive description of its horizontal motion, given that such floor cannot be realistically modelled as a rigid diaphragm due to its geometry and materials. The adopted configuration was possible given that the interested portions of the first floor were safely accessible. Other configurations keeping some of the accelerometers as fixed (reference sensors) and the other as roving sensors, e.g. [5], were not explored given the major difficulties in a safe accessing other areas of the same floor and the impossibility of a safe access to the roof level just above the first floor. Data acquisition was performed at 2048 Hz for about 30 minutes. This duration corresponds to more than 4000 times the fundamental period of the building, as suggested in [7]. Afterwards, the signals were pre-processed to remove the linear trend by subtracting the logged signal with a zero-degree polynomial, filtering with a low-pass filter with a cut-off frequency

of 49 Hz, and a resampling at a frequency of 102.4 Hz to reduce the amount of data and to make subsequent analyses faster.

(a)

(b)

Figure 3: Configuration of the installed 12 accelerometers in preliminary monitoring: (a) position of sensors; (b) example of installations.

The identification of the modal parameters (frequencies and damping ratios) was carried out by the Covariance data driven - Stochastic Subspace Identification (SSI/Cov) [5][14]. Figure 4 shows the stabilization diagram obtained from the tests, where the identification of the stable modes indicated on the graph by a solid black circle, was carried out considering a difference less than 1% in frequency and a MAC greater than 95% on mode shape. The first mode is essentially a translational mode along the X-direction and has an estimated frequency 3.36 Hz (period 0.298 s) and damping ratio 1.86%. The second mode is essentially a transla-

tional mode along the Y-direction and has an estimated frequency 4.52 Hz (period 0.221 s) and damping ratio 3.71%.

Figure 4: Results of preliminary monitoring (June 2020): Stabilization diagram.

### 3.2 Long-term monitoring system and first results of continuous monitoring

The results of the preliminary structural monitoring made in June 2020 provided the support for the definition of a simpler configuration using a limited number of accelerometers in order to reduce the data to be stored and processed. Given that the larger accelerations were measured in points 9, 10, 11 and 12 (according to Figure 3) and that such sensors were able to identify the first modes, the selected configuration for long-term monitoring uses four accelerometers located as depicted in Figure 5a. The adopted accelerometers are uniaxial high sensitivity piezoelectric accelerometers (PCB model 393B31). Environmental parameters are monitored using an independent system comprising two wireless sensors for internal temperature and relative humidity (Elitech RC-51H) as well as a weather station for temperature, relative humidity, wind speed and direction (WatchDog 2700) located just outside the Ducal Palace (Figure 5b). In addition, a triplet of linear potentiometers (Gefran model PZ67-A) were installed across the cracks in the cross vaults in order to measure their movements (Figure 5a). The configuration of the displacement transducers is composed by three linear potentiometers placed across the vaults connected by two galvanised metal sheets (2 mm thickness) to follow the curvature of the vaulting. Each pair of linear potentiometers forms an angle of 60 degrees. Such configuration permits to evaluate every motion of the cracks, such as side scrolling or stretching movements leading to an opening of the crack itself (Figure 6). Besides, image-based monitoring, e.g. [15], is being evaluated to possibly complement contact sensors.

Both accelerometers and linear potentiometers were connected through high-quality shielded cables to the acquisition system (National Instruments cRIO 9045 installed with NI 9234 analogue-to-digital converters for acquiring accelerometers and NI 9209 for acquiring potentiometers). The acquisition procedure was developed in the cRIO 9045 using the programming environment National Instruments LabView to control the entire process, i.e., 30-minute time logging every 2 hours, local data storage, data transfer on cloud storage accessible for remote verifications. The procedure is characterized by a continuous data acquisition of the data and a timing control that activate the logging data; within the logging cycle there is another timing control that stops the logging procedure when the assigned time elapsed. To optimize the accelerometers and linear potentiometers acquisition, the physical channels defi-

nition were divided into two parallel cycles with specific sample clock to synchronize the analogue to digital converters modules (Figure 7).

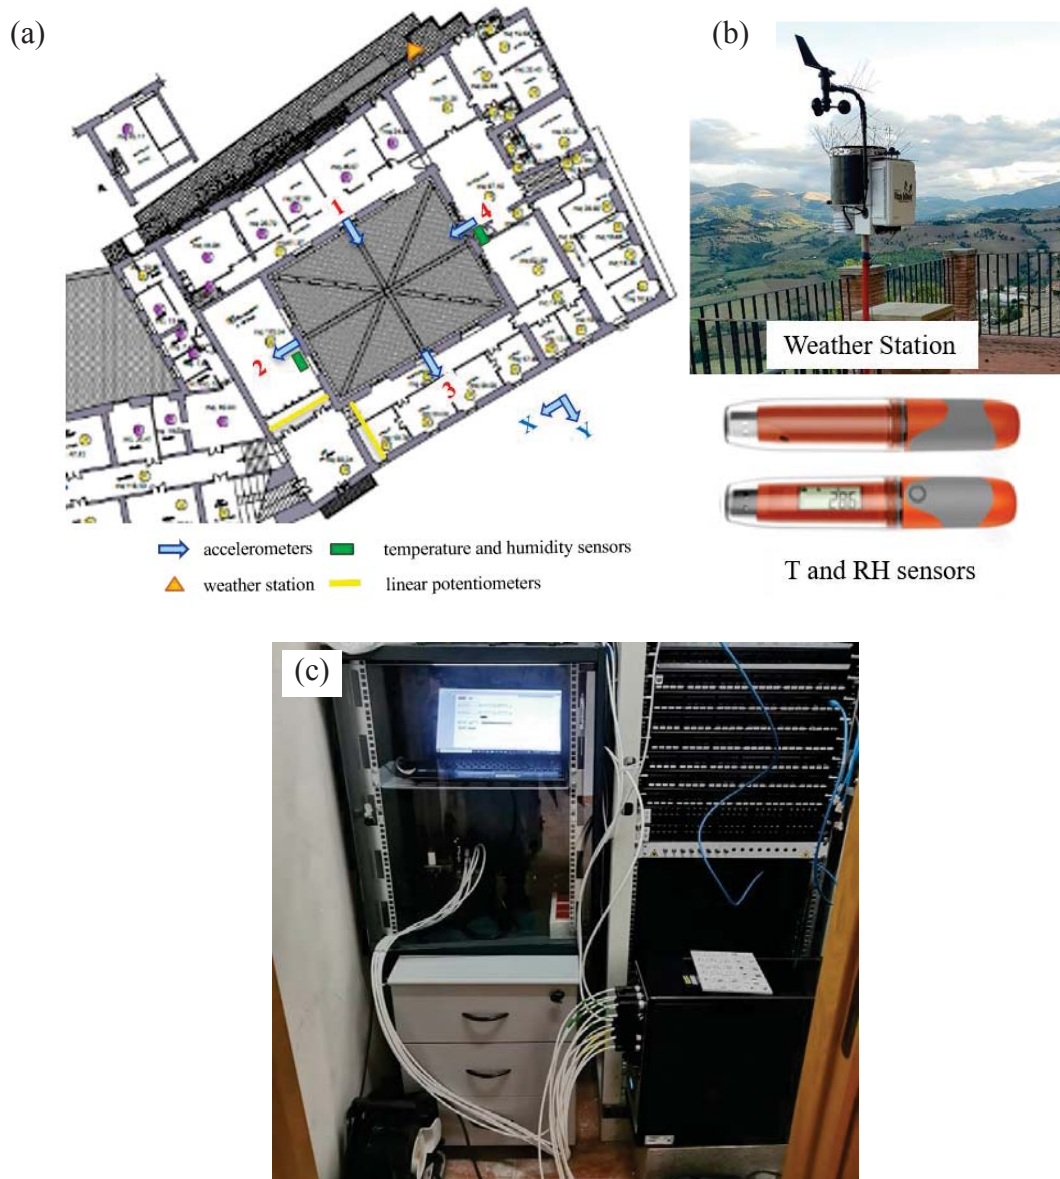

Figure 5: (a) configuration of the sensors position; (b) environmental sensors; (c) acquisition system (laptop, data acquisition module with AD converters, and signal conditioner for linear potentiometers).

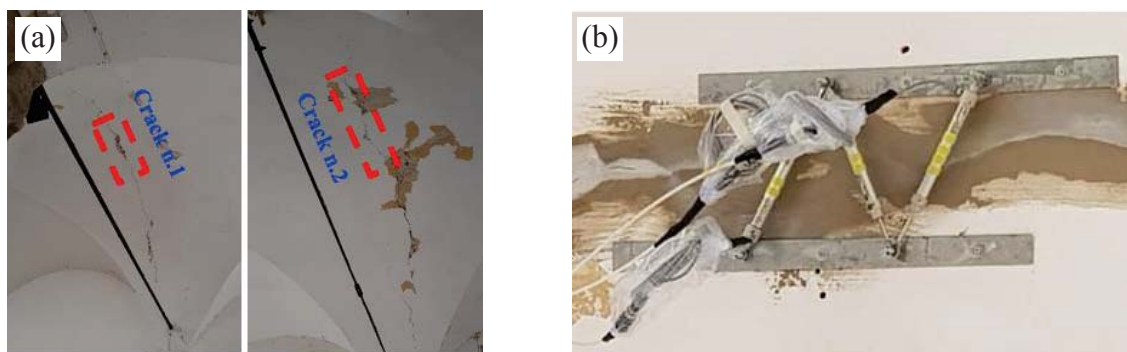

Figure 6: (a) survey of the monitored cracks; (b) arrangement of the triplet of linear potentiometers.

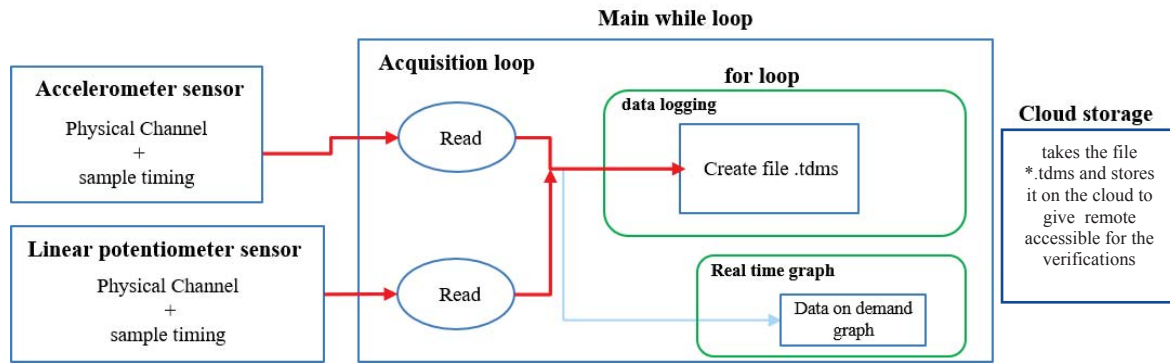

Figure 7: Schematization of the acquisition procedure.

The analysis of the first results is based only on the first month (October 2020) of acquisition of the long-term monitoring system. If attention is focused on the two translation modes identified in the preliminary monitoring described in the previous paragraph, then the results indicate a rather stable trend of the frequencies (Figure 8) with some points missing when the instrument noise was comparable with the background environmental accelerations, making the results of post-processing unreliable. In fact, it should be remarked that the historical centre of Camerino is still a restricted area following the major damages after the 2016 Central Italy earthquakes; this condition makes the area characterized by very low level of environmental noise during the day (a condition possibly exacerbated by the current pandemic restrictions) and even more during the night. At this regard, Figure 9 compares the power spectral density of the signal provided by the same accelerometer in the evening and daytime this highlights the large variation of the signal intensity over the day. Some recordings were excluded in the post-processing because instrument noise was comparable with the environmental accelerations.

Figure 8: Monitored eigenfrequencies in the first month (October 2020).

Figure 9: Comparisons of Power Spectral Densities during daylight and at night.

#### 4 CONCLUSION

This paper described the long-term monitoring system designed and installed in the Portico Varano, the quadriporticus of the Ducal Palace in Camerino (Italy), damaged after the 2016 central Italy earthquakes. The system comprises four high sensitivity accelerometers (whose position was selected after preliminary vibration monitoring tests using twelve accelerometers), a triplet of linear potentiometers installed across the most critical crack in the most damaged cross vault, and environmental sensors (temperature, relative humidity, wind speed and direction). The accelerometers permits to observe the natural frequencies of vibration and relevant mode shapes and damping, providing essential information on the evolution over time of the main structural properties and their variation that can be correlated to the level of damage. The displacement transducers complement the information gained through the accelerometer with a direct measure of the variations of the width of the cracks. The environmental sensors allows to separate the contribution caused by the changes in the temperature and humidity to those related to structural damages as well as the relations between wind intensity and induced structural vibrations. Data recording started in October 2020 and some initial results were discussed. It is observed that the low level of measured vibrations due to restricted access to the Camerino city centre (given the safety concerns after the occurred seismic damages and possibly exacerbated by the current pandemic crisis) poses major challenges to long-term monitoring and enforces the use of high-quality and high-sensitivity sensors connected using highly shielded wires. Nevertheless, stable results were observed during the monitoring time window, constituting a first set of data that could be an essential tool to support model-based simulation for the prediction of the seismic response of the Ducal Palace as well as for the optimal calibrations of the required seismic upgrading interventions.

### Abstract

*In the last years, in Italy, due to the recent catastrophic collapses, an increasing amount of resources has been invested in the maintenance of existing infrastructures. In particular, the monitoring of the structural “health” has assumed a crucial role in the assessment of structures and infrastructures. The technological advancement obtained in the field of informatics and electronic has allowed to move from a discrete and partial control of the structural conditions to a continuous and complete Structural Health Monitoring (SHM). Different techniques may be applied and the Operational Modal Analysis (OMA), among others, aims at identifying the health status of the structure by the modal properties when is under its operating conditions. This paper compares the results of OMA technique using the vibration data obtained by two different sensors equipment applied to an existing bridge located in Benevento, Italy. A dynamic test was performed in 2020 by using a low cost experimental equipment specially designed and developed by the University of Sannio. The tests results have been compared with the data obtained on the same bridge in 2018 by using a commercial and more expensive sensors equipment. The main purpose of the comparison is to support the “homemade” equipment development identifying the aspects on which to improve the same.*

**Keywords:** SHM, OMA, low cost sensors, data processing.

## 1 INTRODUCTION

A large number of road infrastructures has widely overcome 50 years of service design life and need urgent prevention and control measures. Following the critical events occurred in the last years to several highway infrastructures, the issue of their maintenance has assumed a primary role [1]. The interest is very significant since they are not single punctual elements but are part of a more extensive network. Hence, the potential disruption could have exceptional consequences in both the economic and social sides, proportionally to the importance of the infrastructure itself. Structural damage depends on several elements as, among others, quality and type of materials, age, construction techniques, loads level and environmental conditions. Generally, degradation or damaging phenomena can be responsible to modify the mechanical properties of the materials [2]. In reinforced concrete elements, the corrosion of the steel bars is the main cause of degradation phenomena. Due to the porosity of concrete, some chemicals including carbon dioxide, oxygen and water, can penetrate the material triggering the carbonation process. Chloride ions, if passing a critical concentration threshold [3], perforate the protective oxide film surrounding the rebars, starting the corrosion phenomena. The latter case is typical of bridges that are subjected to winter frosts and are generally kept operational using de-icing salts. The same is true for all those structures located in coastal areas or directly exposed to seawater [4].

From here, the necessity of checking the “structures health” by using effective monitoring systems. The most appropriate monitoring system depends on many factors. Traditional checking and monitoring methods for infrastructures rely on visual inspections, but they often lead to a temporary interruption of use and must be carried out by highly qualified personnel. Furthermore, mainly due to the subjectivity of the evaluation, it is difficult, using this technique, to obtain an effective monitoring over time [5]. Hence, with the main target to provide automatic tools useful for observing the evolution of degradation phenomena in support of traditional techniques, many others elaborate methods were developed [6, 7]. When the devices that allow the loading and damaging condition of a structure to be recorded, analyzed, localized and predicted, become an integral part of the structure, the monitoring approach is called Structural Health Monitoring (SHM) [8]. The SHM is a process based on a series of axioms [9] and phases [10] widely applied in various engineering sectors due to its ability to respond to adverse structural changes, improving structural reliability and life cycle management. To implement a SHM system, several components, such as sensors, data acquisition, transmission system and software for data processing, are needed. By analyzing data collected from sensors, it is possible to identify any damaging in progress and evaluate the structural performance both in operating and in exceptional (e.g. earthquakes or after earthquakes) conditions. The number of sensors to use depends on the structural dimension. For long structure as a bridge, it can represent a very expansive cost. For this reason, the development of low cost and easy to install sensors can be a fundamental target in the SHM applications. This work shows the results obtained by applying a network of nine prototype accelerometer sensors with these characteristics to an existing RC bridge located in south Italy.

## 2 OPERATIONAL MODAL ANALYSIS

The dynamic behavior of a structure depends on mass, stiffness, damping and nevertheless by external and internal constraints. These properties give information about the free vibration response, therefore, if they do not change (e.g., as a result of structural damages), the dynamic characteristics remain the same. Generally speaking, the analysis of the dynamic behavior of a structure can be addressed using analytical or experimental approaches. For bridges, the most used technique in experimental approaches is the Operational Modal Analysis (OMA). It allows to identify the modal parameters of the structures [11, 12, 13] based on vibration data collected when the structure is under its operating conditions, i.e., vehicular traffic, wind, etc. It relies on a series of basic assumptions such as linearity, stationarity, observability [14, 15]. OMA test is a suitable technique for SHM because interruption of the structure use is not required. Sensors can be permanently installed to identify changes in the dynamic properties. On the other hand, unknown load conditions can make it more difficult for the processing phase. Over the last few decades, several mathematical methods have been developed to determine the modal parameters of the structure by OMA methodology (time or frequency domain, SDOF or MDOF methods, etc.).

In frequency domain, the Frequency Domain Decomposition (FDD) consists of the identification of the peaks of the Power Spectral Density (PSD) matrix of output. The basic assumption is that the resonance response is dominated by the contribution of the mode whose natural frequency is closest [16]. The contribute of the other modes is negligible, and therefore, FDD is classified as SDOF method. This method gives good results for structures having well-separated modes and with non-negligible damping. FDD method relies on the Singular Value Decomposition (SVD) of the PSD matrix at a specific frequency  $f$  [17] and allows to define resonance frequencies and mode shapes, but not modal damping. Modal damping ratio can be found by using the so-called Enhanced Frequency Domain Decomposition (EFDD) method. It is an improvement of the FDD method that uses the singular vector defined in FDD application but relies on the so-called Modal Assurance Criterion (MAC) that allow to compare the modes shape  $\{\phi_r\}$ . The MAC number is defined as:

$$MAC(\{u_j\}; \{\phi_r\}) = \frac{|\{u_j\}^H \{\phi_r\}|^2}{(\{u_j\}^H \{u_j\}) (\{\phi_r\}^H \{\phi_r\})} \quad (1)$$

where  $\{u_j\}$  is the generic singular vector closed to the peak response corresponding to the  $r$ -th mode  $\{\phi_r\}$  and  $H$  is the symbol to indicates the conjugate and transpose operator. MAC is a useful statistical indicator for the quantitative comparison between modal vectors. It ranges between 0, namely the modes are completely unrelated and 1 which means that the modes perfectly match [18]. Finally, the Curve-Fitting Frequency Domain Decomposition (CFDD) is a parametric technique that relies on the curve-fitting of the PSD function in the frequency domain. Consequently, a more accurate estimation of frequencies and damping ratios is obtained [19].

Time-domain methods are based on the analysis of time histories or correlation functions. The most used is the Stochastic Subspace Identification (SSI) which most common declinations are the Unweighted Principal Component (SSI-UPC) and the Principal Component (SSI-PC). The difference between the SSI approaches is the weight matrixes to use for the determination of the observability matrix. Indeed, in SSI method the projection of the future unto the past (respectively the lower and the upper part of the Block Hankel matrix) defines a matrix so called "O" which columns represent a stacked free decay of the system to a set of unknown initial conditions. Since the observability matrix is unknown it is necessary to pre and post-multiply the matrix O by the so-called weight matrixes and then to apply the SVD to it [20].

### 3 THE CASE STUDY

The results of OMA technique using the vibration data obtained by two different experimental sensors equipment applied to an existing bridge located in Benevento (Italy), are herein proposed and compared. The case study is the so-called San Nicola Bridge, located in Benevento as part of the main street S.S. 90 bis and spans river San Nicola (Figure 1).

Figure 1 – *San Nicola Bridge. Global (left) and street (right) views*

The bridge was designed by the famous engineer Riccardo Morandi between 1952 and 1955 and built between 1955 and 1956. The static scheme is a portal frame composed by one main span 80.0 m long and two cantilevers of 20.0 m (Figure 2). The deck consists of four prestressed box-girders, whose webs vary in thickness, from a minimum of 13 cm at the midspan, to a maximum of 30 cm at the supports, and it is supported by two piers 9.40 m high and linked to the foundations underneath by hinges made of steel rebars. Each pier consists of eight columns of rectangular section, 40.0 cm thick and variable width from 1.50 m at the base to 4.00 m at the top, that are connected at the base and top by a transverse beam. The width of the upper slab is 9.00 m and consists of two traffic lanes, 7.00 m width, and two sidewalks 1.00 m width on both sides. Plan and prospectus of the bridge are reported in Figure 3.

Figure 2 – *Bridge pier (left), bridge deck (right)*

Figure 3 – San Nicola bridge plan and prospectus view

Following the collapse of the Polcevera viaduct (designed by the same engineer Riccardo Morandi) occurs in Genoa (Italy) on 14 August 2018, the bridge was closed as a preventive measure from August to December 2018. To determine the health status of the bridge, a series of tests were carried out by the Department of Engineering of the University of Sannio. In particular, a dynamic test to identify fundamental frequencies and mode shapes of the bridge was performed in 2018 and subsequently replicate in 2020. A finite element model has been also developed by CSiBridge software [21] using shell elements for the deck, frame elements for the piers and modelling the prestressing cables as tendon. Model calibration using the results coming from the experimental campaign was performed in [22]. Modal analysis results are reported in Figure 4. As evident, the first mode is transversal, with frequency 1.91 Hz, the second vertical (2.16 Hz) and the third torsional (4.16 Hz).

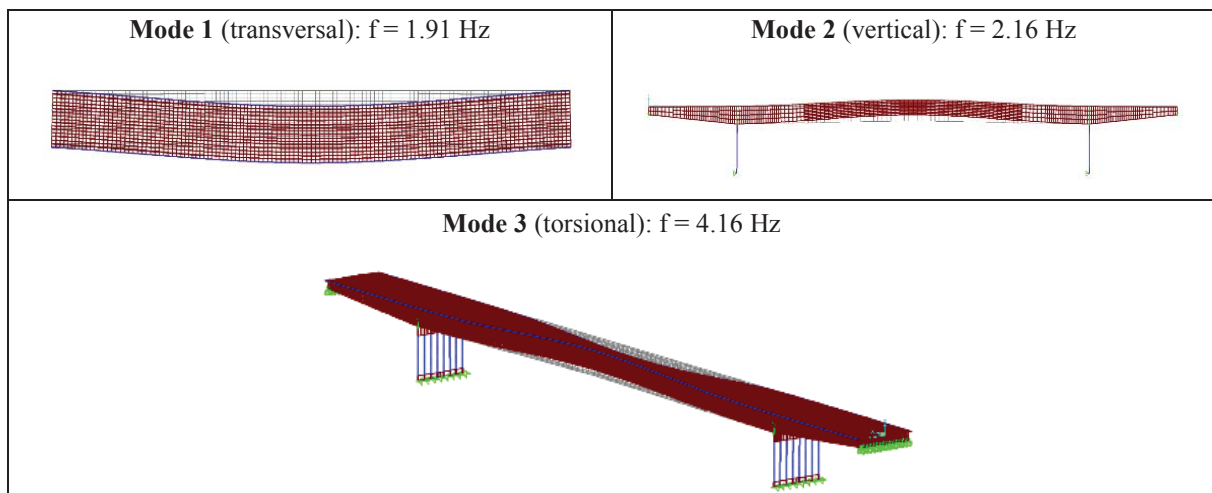

Figure 4 – Mode shapes and frequencies analysis results

#### 4 EXPERIMENTAL TESTS DESCRIPTION

In 2018 and 2020, dynamic tests were performed on San Nicola Bridge by using a commercial and prototype experimental equipment respectively. For safety, in both cases the bridge was closed to traffic, that means vibrations were caused just by environmental noise. The recorded row data have been pre-processed by filtering and resampling operations by MATLAB [23] and subsequently analyzed by the specific software ARTeMIS [24] to find the modal parameters of the structure.

In particular, on December 2018, the test was performed by the commercial and certified equipment of SEQUOIA manufacturing [25]. The system consists of a network of five sensors (called GEA II sensor) connected by cables to a data acquisition device (DAQ) (Figure 5). Designed to permanent or semi-permanent installations, its size is about 60x30x40 cm for the DAQ device and about 11 cm of diameter for the sensors (Figure 5). The commercial cost of the equipment is about 50'000 euros.

Figure 5 – GEA II sensors and DAQ

On September 2020, the dynamic test on the same bridge has been replicated by a prototype low-cost and no wired system (Figure 6) called SENTINEL properly developed by the Department of Engineering of the University of Sannio. The system consisted of a network of nine high sensitivity accelerometers capable to record structural vibrations. No data acquisition (DAQ) has been used: each device already has on board all that is needed to be an independent accelerometric station. The devices allow to set specific technical parameters as the sampling frequency (choosing between 125, 250, 500 and 1000 Hz), the full-scale range (choosing between 1, 2, 4 and 8 g), the file duration recording (the interval of data storing). The sensors are equipped with an internal battery, a micro-sd card slot, a router UMTS/WIFI, a GPS receiver, a microprocessor and a MEMS accelerometer (Figure 7). An autonomy of 24 hours recording time is guaranteed. The small size (21x15x7 cm) and the low weight (about 2 kg) of the device makes it very easy to manage. The assumed commercial cost for each prototype device is about 500 euros (a total cost equipment of about 5'000 euros is estimated).

Figure 6 – *SENTINEL* deviceFigure 7 – *SENTINEL* device components

The devices have been fixed to the deck of the bridge by two screws (Figure 8). Three different setups were performed modifying their position except for the reference sensor (R) that remained in the same position for the entire experimental campaign. In Figure 9, the position of the sensors for each setup is reported. To note that S means sensor, the first number indicates the setup, the second the id of the sensor; the reference sensor is identified by the letter R. The total number of the recorded points is 25. The spacing among sensor positions is from a minimum of 6 to a maximum of 12 meters for both sides of the bridge (A and B).

The signals have been recorded for 30 minutes for each setup at 125 Hz sampling rate.

Figure 8 – *Installation: device detail (left) and global view (right)*Figure 9 – *Position of sensors for each setup in the 2020 experimental campaign*

## 5 RESULTS OF THE EXPERIMENTAL CAMPAIGN USING PROTOTYPE EQUIPMENT

The dynamic characteristics of the bridge obtained by the experimental campaign performed in 2020 using the prototype equipment have been evaluated by the software ARTeMIS. In particular, the mode shapes associated with the first two modes (transversal and vertical modes respectively), obtained applying the FDD method and normalize to one magnitude, are represented in Figures 10 and 11 for both sides A and B of the bridge separately. The black and the red continues lines, indicated the undeformed and the mode shapes respectively. Specifically, mode shapes represented by the dashed red lines are the first result of the row data elaboration. As evident the mode shapes are not clearly defined that is are not well-separated from each others. This is due to the absence of a DAQ device with the specific assignment to synchronize starting record of a system with multiply measure points. This problem has been partially solved by knowing the instant of time at which the last sensor has started the recording and manually cutting all the data stored by the other stations before this time. Furthermore, due to hardware problems, the sampling frequency was not constant. Specifically, even if the sampling rate has been set the same for all devices (i.e. 125 Hz), the effective values have been different. Hence a resampling has been applied. The new mode shapes obtained after the synchronization procedure are represented as red continue lines in Figures 10 and 11. As evident, a good improvement was obtained for the first mode (transversal), especially for side A. Some discrepancies are still present at side B, that is two vectors have an opposite direction than expected (Figure 10). The same good results were found for the second modal (vertical) shape for side B while for side A some vectors have an unexpected direction (Figure 11).

Figure 10 – Mode 1 (transversal): Comparison between unsynchronized (dashed red line) and synchronized (red line) mode shapes obtained applying FDD method

Figure 11 – Mode 2 (vertical): comparison between unsynchronized (dashed red line) and synchronized (red line) mode shapes obtained applying FDD method

For different frequency-domain methods applied (FDD, EFDD, CFDD), transversal mode frequency values are very similar (1.26, 1.27 and 1.26 Hz respectively) and closed to analytical result (1.91 Hz). However, applying time-domain methods no transversal mode have been founded. A maximum difference about 10% has been obtained for frequency values associated with the vertical mode (2.23-2.45 Hz). Finally, frequency values related to the torsional mode show modest difference (5.23-5.65 Hz) but are quite far from analytical value (4.16 Hz). Table 1 summarizes these results.

OMA method	Mode 1 (transversal)	Mode 2 (vertical)	Mode 3 (torsional)
<i>FDD</i> [Hz]	1.26	2.23	5.46
<i>EFDD</i> [Hz]	1.27	2.23	5.46
<i>CFDD</i> [Hz]	1.26	2.22	5.46
<i>SSI-UPC</i> [Hz]	-	2.37	5.24
<i>SSI-PC</i> [Hz]	-	2.45	5.23
<b>Max variation [%]</b>	<b>0.08</b>	<b>10.16</b>	<b>4.38</b>
<i>Analytical results</i> [Hz]	1.91	2.16	4.16

Table 1 - Results of 2020 experimental campaign in terms of frequencies

Modal forms obtained using frequency domain (FDD, EFDD, CFDD) and time domain (SSI-UPC, SSI-PC) methods are compared in Figures 12 and 13. As shown, all the methods have given, as first mode, the same results. Small differences were found in the vertical mode. For the third mode, as expected, the methods failed to provide a unique solution.

Figure 12 – Mode 1 (transversal): comparison of mode shapes obtained applying different OMA methods

Figure 13 – Mode 2 (vertical): comparison of mode shapes obtained applying different OMA methods

The validation of the obtained results has been carried out by the MAC number, already described in section 2. First of all, a comparison between all the combinations of mode shape pairs calculated using a single technique is made (AutoMAC criterion). As shown in the left part of Figure 14, second and third unsynchronized mode shapes are not well-separated from each other (MAC values outside the main diagonal are about 0.5 for all techniques). After the synchronization procedure, an important improvement was obtained: the MAC values outside the main diagonal are very close to zero (right part of Figure 14) except for the SSI-PC method, where second and third modes remain very similar to each other despite the synchronization procedure.

Figure 14 – Validation: comparison between MAC numbers for unsynchronized (left) and synchronized (right) mode shapes (data labels indicate the MAC numbers)

In Figure 15 the “CrossMAC” criterion results are reported for synchronized mode shapes. It consists of comparing sets of modes calculated by different OMA techniques. High values mean a good estimation for the mode shapes. As evident, the results are good since MAC values are very high with a limited range 0.87 – 1.00, except for the third mode in SSI technique (values close to 0).

Figure 15 – Comparison between MAC numbers using different techniques for synchronized mode shapes (data labels indicate the MAC numbers)

## 6 COMPARISON BETWEEN COMMERCIAL AND PROTOTYPE EQUIPMENT TEST RESULTS

The results of the test performed by using the prototype equipment in 2020 have been compared with those obtained on the same bridge in 2018 by using a commercial sensors equipment. In terms of frequencies, a good correlation has been found for all the OMA techniques (a difference lower than 7% is appreciated) except for the SSI-UPC method, where an important difference of about 25% is noted for the second (vertical) mode (Table 2).

OMA method	Mode 1 (trasversal)			Mode 2 (vertical)			Mode 3 (torsional)		
	$f_{\text{prototype}}$	$f_{\text{commercial}}$	Variation	$f_{\text{prototype}}$	$f_{\text{commercial}}$	Variation	$f_{\text{prototype}}$	$f_{\text{commercial}}$	Variation
	[Hz]	[Hz]	[%]	[Hz]	[Hz]	[%]	[Hz]	[Hz]	[%]
FDD	1.26	1.18	6.60	2.23	2.16	3.20	5.46	5.65	5.46
EFDD	1.27	1.18	6.93	2.23	2.12	5.00	5.46	5.65	5.46
CFDD	1.26	1.18	6.85	2.22	2.12	4.81	5.46	5.65	5.46
SSI-UPC	-	-	-	2.37	1.89	25.44	5.24	5.65	5.24
SSI-PC	-	-	-	2.45	2.32	5.47	5.23	5.67	5.23
Analytical result	1.91			2.16			4.16		

Table 2 - Comparison between modal frequencies obtained by prototype and commercial equipment

A comparison between modes defined using prototype (red line) and commercial (blue line) equipment and analytical predictions (dashed blue line) is reported in Figures 16 and 17. For the first mode, except for some points, the shapes are completely overlapping (especially for the side A). For the second mode, the results are very good for the side A, while for the side B, no good result was obtained: the vectors have a direction that is opposite than expected.

Figure 16 – Mode 1 (transversal): comparison between mode shapes defined using prototype equipment (red line), commercial sensors (blue line) and analytical calculation (dashed blue line)

Figure 17 – Mode 2 (vertical): comparison between mode shapes defined using prototype equipment (red line), commercial sensors (blue line) and analytical calculation (dashed blue line)

## 7 DISCUSSION AND CONCLUSIONS

In this paper, the effectiveness of a wireless, low-cost and easy to install monitoring system, is evaluated. The system is a prototype consisting of nine accelerometric sensors developed by the Department of Engineering of the University of Sannio. Specific problems due to the synchronization among the devices have been addressed and solved. The equipment was tested by performing a dynamic identification test on an existing bridge located in Benevento, Italy. Two experimental mode shapes were found and validated using MAC number. The tests results have been compared with the data obtained on the same bridge in 2018 by using a commercial sensors equipment. Results demonstrate the effectiveness of the prototype system. Future developments concerning the modification of the hardware apparatus in order to solve some occurred problems have been already addressed.

### Abstract

*Historical masonry structures constitute a fundamental part of the built cultural heritage but are characterized by an intrinsic vulnerability to ageing and natural hazards, in particular to earthquakes. The related need to assess their current health condition and to ensure their future conservation is giving rise to increasing efforts in scientific research. The combined employment of health monitoring systems and structural modelling is widely adopted in this field, either to better interpret the effects of age-related degradation or to reliably predict the structural response to earthquakes. Both scenarios can leverage experimental measurements for the model calibration, thus reducing epistemic and aleatory uncertainties in the assessment phase. Among the available modelling strategies, refined Finite Element (FE) models represent the most common choice in the SHM perspective for monumental URM structures. Nonetheless, the computational effort required by the assessments in the nonlinear field – unavoidable in seismic evaluations – is often unfeasible, especially in practice engineering. In the case of palaces, an alternative is the employment of more computationally efficient formulations such as Equivalent Frame (EF) models. Within this framework, the paper firstly deals with the equivalent-frame modelling and model updating of the Consoli Palace, a historic masonry building in Gubbio (Italy) investigated through ambient vibration tests. The peculiar aspects of the building – e.g. the unusually high inter-storey height, the presence of vaulted floors, the irregular distribution of the openings – make the equivalent-frame idealization a challenging task. The comparison with a detailed finite element model developed in previous research points out the differences and limits of the two approaches, providing some suggestions to benefit from their integrated use.*

**Keywords:** historical masonry buildings, Structural Health Monitoring, Equivalent Frame models.

---

## 1 INTRODUCTION

Masonry structures constitute probably the largest part of the worldwide built heritage. Being masonry one of the oldest materials employed to build by humankind, this structural typology is commonly characterized by exceptional historical, cultural and architectural value. For these reasons, structural health assessment, conservation and rehabilitation of the built masonry heritage are crucial responsibilities of today's society. The statement is relevant both from a social and an economic point of view, urging for the efforts of the scientific community to address these tasks. Indeed, because of their age, old masonry structures suffer today the effects of ageing and deterioration over the past centuries, together with the succession of countless anthropic modifications and the constant acting of natural phenomena. These aspects, considering the intrinsic complexity of old masonry structures, make their structural health assessment a challenging goal.

In this context, the employment of non-destructive experimental techniques is leading the Structural Health Monitoring (SHM) research field, aimed at supporting the engineering judgment through experimental evidence. Together with the measurement of environmental factors, a primary role is played by dynamic testing through permanent monitoring systems, allowing for real-time identification and tracking of the dynamic properties of existing structures. Dynamic properties, indeed, are those commonly assumed as the *proxy* of structural health, so that detection of their variations corresponds to the potential – such as the occurrence of damage.

If the main trends of the research [1] follow the employment of *data-driven* statistical methodologies aimed at unsupervised evaluations, not less important is the complementary employment of engineering-based *model-driven* approaches, relying on accurate mechanical models for the simulation of the structural behaviour. In the case of historical masonry structures, among the possible modelling strategies (reviewed in [2][3] and discussed in [4] from a seismic engineering perspective), the common approach relies on refined Finite Element (FE) models, allowing for a detailed idealization of the structure. Such a potential, commonly, comes at the cost of (i) a large set of input parameters and (ii) high computational requirements, which often makes the employment of FE models unfeasible – for example, in nonlinear seismic analyses.

In the case of palaces, on the other hand, an alternative option is provided by Equivalent Frame (EF) models, specifically addressed to the analysis of the global seismic response of ordinary masonry buildings. This modelling technique discretizes the masonry continuum as an assemblage of macroscopic structural elements. Being governed by few mechanical parameters and a limited number of elements, EF models are an attractive choice thanks to their computational efficiency [5]. Nonetheless, as discussed in the following Sections, the common simplifying assumptions of this approach challenge its applicability in the case of monumental masonry palaces.

Based on the above presented motivations, the paper addresses the employment of EF models to support the SHM in the case of masonry palaces, proposing some preliminary considerations through the comparison with more refined FE models. In particular, the historical *Consoli Palace* of Gubbio, Italy, is chosen as the suited case study (§2). The three-dimensional FE of the palace, previously developed and dynamically calibrated by the University of Perugia research group, is assumed as the reference result (§3.2). An EF formulation of the palace is proposed, highlighting some possible issues related to common modelling assumptions (§4.1). The model is dynamically calibrated based on the results of AVTs employing a global search algorithm, taking into account the uncertainties related to the limited knowledge of the mechanical properties of the existing structure, as well as those produced by the EF idealization (§4.2). The dynamics of the updated model is satisfyingly close to the experimental evidence and the set of optimal parameter points out the importance of the out-of-plane stiffness contribution of

masonry walls (§4.3). A final comparison between the updated models shows good accordance in terms of dynamic and seismic properties (§4.4), confirming the possibility of their integrated use in the SHM perspective and pointing out interesting developments of the research (§5).

## 2 THE CONSOLI PALACE OF GUBBIO, ITALY

The Consoli Palace (Figure 1a), located in the medieval town of Gubbio (Central Italy) is a monumental palace built between 1332 and 1349 according to different architectural building styles. The whole structure (Figure 1b) is mainly made of calcareous stone masonry also in the newest parts, as the staircase of the main façade, which is characterized, in the upper part, by coupled round-arched windows separated by *lesenes*. Above them, merlons enclose the rooftop and the bell tower. The lower part of the main façade is characterized by mullioned windows, a Gothic-style portal and the main staircase.

The palace has a 40x20 m rectangular plan and an elevation of about 60 m. The structure is arranged on different floors: two levels on the foundation system; the *Arengo hall* at a height of 4.64 m, accessible from the principal staircase (Figure 1c); the *Nobili hall* at a height of 18.89 m (Figure 1d); the rooftop at a height of about 30 m. The Arengo hall, in particular, develops seamlessly – i.e. without intermediate walls – thanks to the huge structural thickness of the perimetral walls, which support a huge barrel vault. The Southside of the Palace is characterized by the *loggia*, a not-in-built architectural portion.

A recent in situ survey has allowed identifying different connection degrees between structural elements (walls-to-walls, walls-to-vaults) standing from interlocking to simply leaning elements. Moreover, the external stones of the Palace exhibit an apparent state of degradation, possibly attributed to exposition to environmental stresses and pollutants, such as biological patina, black crust, presence of vegetation, spalling, reintegration and encrustation.

### 3 TARGET DYNAMIC DATA AVAILABLE FOR MODELS' CALIBRATION AND COMPARISON

#### 3.1 Dynamic identification from Ambient Vibration Tests (AVTs)

The dynamic properties of the Consoli Palace were investigated through Ambient Vibration Tests (AVTs) carried out on May 4<sup>th</sup>, 2017. The main purpose of the AVTs was the identification of the elastic dynamic properties of the structure, i.e., natural frequencies, mode shapes and damping ratios, for structural monitoring and finite element model calibration purposes.

According to the hypothesis of in-plane rigid behaviour of the horizontal floor diaphragms, a network of 9 uni-axial high sensitivity piezoelectric accelerometers – model PCB 393B12, capable of measuring maximum accelerations of  $\pm 0.50$  g with a sensitivity of 10 V/g – were deployed on the three main floors of the Palace (rooftop, Arengo hall, Nobili hall, Figure 2).

The AVT was conducted by using a multi-channel data acquisition system characterized by 24-bit resolution, 102 dB dynamic range and anti-aliasing filters.

The modal identification of Consoli Palace was performed by considering accelerations induced by micro-tremors, mainly due to wind and weak traffic excitation coming from the neighbouring area around the Palace. Consecutive time windows of 1800 s were collected, corresponding to more than 4000 times the fundamental period of the building.

The acceleration responses of the palace were recorded with the hardware own sampling frequency of 1652 Hz. Then, since the dominant natural frequencies were expected to lay below 10 Hz, signals were down-sampled to 40 Hz after low-pass filtering, with a Nyquist frequency of 20 Hz.

The acquired signals were affected by anomalous peaks due to the bells-dependent non-stationary excitation, produced by the bell tower playing all day and night long with a 15-minute step interval. To remove this effect, an automated simple pre-processing tool has been implemented and applied to the data enabling to identify portions of the signals containing peak response accelerations overcoming a prescribed threshold (assumed as ten times the root mean square value of the signal) and to remove these portions – after application of half Hanning windows to the tails of the signals to be concatenated.

Finally, the dynamic identification was performed employing the Stochastic Subspace Identification (SSI) technique. To briefly introduce the SSI methods, it is convenient to consider a time-invariant  $n$ -dof structural system, whose state-space equations of motion can be written as

$$\begin{aligned} \mathbf{x}(k+1) &= \mathbf{A}\mathbf{x}(k) + \mathbf{w}(k) \\ \mathbf{y}(k) &= \mathbf{C}\mathbf{x}(k) + \mathbf{v}(k) \end{aligned} \quad (1)$$

where  $k$  denotes the time step;  $\mathbf{x} \in \mathbb{R}^n$  is the state vector;  $\mathbf{y} \in \mathbb{R}^l$  is the vector of the  $l$  output measurements;  $\mathbf{w} \in \mathbb{R}^n$  is the external input, modelled as a white noise process vector;  $\mathbf{v} \in \mathbb{R}^l$  is a white noise affecting the measurements;  $\mathbf{A} \in \mathbb{R}^{n \times n}$  is the system matrix;  $\mathbf{C} \in \mathbb{R}^{l \times n}$  is the output matrix. Then, thanks to a transformation of the state-space system, rewritten in the frequency domain by its transfer function through the so-called Canonical Variate Analysis (CVA) algorithm, the modal features can be extracted. More extensive details on this modal identification tool are reported in [6]. Table 1 summarizes the AVT-based fundamental vibration modes, where directions  $x$  and  $y$  are defined along the larger and the smaller dimension of the rectangular plan, respectively. The global mode shapes, i.e., 1-2-5, identified by the adopted SSI procedure are presented in Figure 3.

Figure 2: Configuration of 9 accelerometers and data acquisition system adopted in the AVT (a) at the top of the building (channels 1, 2, 3), (b) in the Arengo hall (channels 7, 8, 9), (c) in the Nobili hall (channels 4, 5, 6).

Mode	Type	Description	$f_e$ (Hz)	$\xi_e$ (%)
1	global	flexural along $x$ -direction	2.296	1.121
2	global	flexural along $y$ -direction	2.989	0.751
3	local	flexural of the bell tower	3.508	0.779
4	local	flexural of the bell tower	3.743	2.477
5	global	torsional	4.172	1.104
6	local	torsional of the bell tower	7.035	1.089

Figure 3: Global mode shapes of Consoli Palace identified from AVT acceleration records by automated SSI. (a) Mode 1, (b) mode 2 and (c) mode 5.

### 3.2 Updated Finite Element (FE) model of the palace

To perform a consistent interpretation of the identified vibration modes, a 3D numerical Finite Element (FE) model of the structure has been built in the ABAQUS environment [7]. The mesh of the model is composed of a dense grid of tetrahedral elements (see Figure 5a in §4.1). Based on the principal architectural portions identified within the building (as described in §2), the model has been subdivided into four homogenous parts characterized by different values of Young's modulus of the masonry: the foundation level, the Arengo level, the Nobili level and the bell-tower. Hence, Young's moduli are assumed as uncertain parameters and their values have been adjusted in the calibration process to minimize the average relative difference

between numerically predicted and experimentally identified natural frequencies. On the contrary, the same values of Poisson's coefficient and material density have been considered in the whole building.

The updated values of Young's moduli are summarized in Table 2. The relative difference  $\Delta f$  between experimentally identified ( $f_e$ ) and numerically predicted ( $f_{n,FE}$ ) natural frequencies is highlighted in Table 3. Extensive details on the FE model calibration can be found in [8].

Part	Initial value (MPa)	Updated value (MPa)
Foundation level	2440	3327
Arengo level	2440	3510
Nobili level	2440	3327
Bell tower	2440	3450

Table 2: Updated values of Young's moduli.

Mode	$f_e$ (Hz)	$f_{n,FE}$ (Hz)	$\Delta_f$
1	2.296	2.352	0.024
2	2.989	3.047	0.019
3	3.508	3.460	-0.014
4	3.743	3.544	-0.053
5	4.172	4.171	<0.001
6	7.035	7.09	0.008

Table 3: Comparison between experimentally identified ( $f_e$ ) and numerically predicted ( $f_{n,FE}$ ) natural frequencies, where  $\Delta_f = (f_n - f_e)/f_e$  represents the relative frequency difference.

## 4 FORMULATION AND CALIBRATION OF THE EQUIVALENT FRAME (EF) MODEL

### 4.1 Equivalent-frame modelling assumptions and related issues

The structural model of the Consoli Palace, based on the Equivalent Frame (EF) modelling approach, is built with the commercial software 3Muri (Release 11.5.7) distributed by S.T.A. Data. In the EF approach, as known, the deformability and the nonlinearity are concentrated in specific parts of the masonry walls, i.e. piers and spandrels. These are the portions in which seismic damage tends to concentrate, as widely testified by in situ observations of existing buildings hit by recent earthquakes (for example, in Italy [9][10][11][12]). According to this idealization, the *piers* – vertical portions of masonry between horizontally aligned openings – resist both vertical and horizontal loads, whereas the *spandrels* – horizontal portions of masonry between vertically aligned openings – play a primary role in piers coupling. The remaining portions of the walls are idealized as *rigid nodes*.

The EF approach, thus, is commonly employed to simulate the global seismic response of ordinary masonry buildings. Some of the simplifying assumptions adopted by EF models, on the other hand, make their application more involved – and sometimes unsuitable – for historical monumental buildings. This is the case of the Consoli Palace, for which the EF approach requires particular caution and poses interesting engineering challenges. The following paragraphs address some of the issues faced in the synthetic EF description of the palace, highlighting the differences with more detailed FE approaches and proposing some possible modelling solutions.

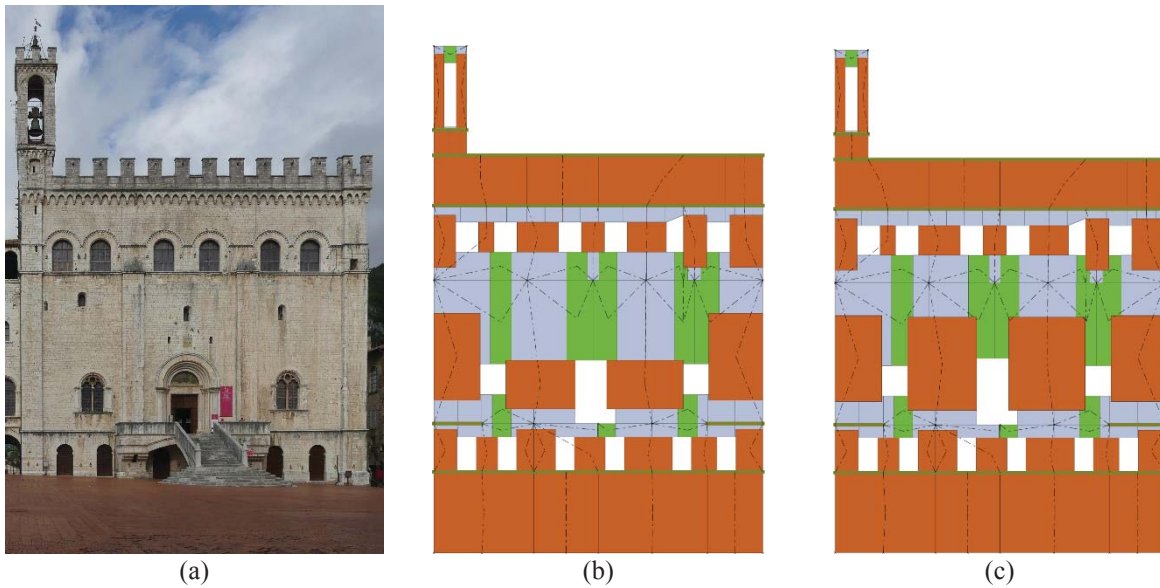

Figure 4: (a) Rectified picture of the Consoli Palace façade. Corresponding EF mesh according to (b) the criteria implemented in 3Muri and (c) after manual modification. The colours orange, green and light blue represents respectively piers, spandrels and rigid nodes.

The definition of the geometry of the vertical structural elements (Figure 4), mainly depends on the number and arrangement of openings. This procedure is straightforward when openings are aligned and regularly distributed. Conversely, in the case of irregularly shaped and sparse openings, the EF modelling becomes non-trivial and requires expert engineering judgment – due to the potential source of large dispersion in the simulation of the seismic response [13][14]. Indeed, the structural mesh significantly influences the static and dynamic behaviour of the structure in the linear and nonlinear regime, so that appropriate criteria for its definition are crucial to obtain reliable simulations.

Several contributions of the literature address this task, providing various indications [15][16][17][18] for the definition of the EF mesh geometry. Nonetheless, most of the rules have been developed based on a regular arrangement of the openings. Among those, recent research [19] and detailed comparisons with cracking patterns of damaged buildings [14] suggest the criterion implemented by 3Muri software to be reliable. Defining the effective height of piers is particularly challenging when the layout of the openings is irregular, which unfortunately represents a recurrent situation in existing buildings. In recent years, many researchers have focused their efforts to overcome this issue (see for example [20][21][22][23][24][25]). However, no shared consensus in the scientific community and standardized rules have been established yet.

The openings of the Consoli Palace are often irregularly arranged on the walls, without systematic horizontal and vertical alignments. In this case, according to the criterion adopted by 3Muri software, large portions of the walls would be idealized as rigid nodes due to the unusually large interstorey heights (such as those of the Arengo hall, §2). In light of these issues, firstly, some very small openings on the perimeter of the palace have been neglected to enhance the quality of the meshing. As shown by recent studies [25][26], this simplification is acceptable when the opening is sufficiently smaller than the masonry panel. Secondly, the software-generated mesh (Figure 4b) has been carefully revised and manually edited, to define deformable masonry portions more consistent with physical expectations (Figure 4c).

For what concerns the floor diaphragms, they are modelled as rectangular orthotropic membranes [15]. Their elastic mechanical properties are identified by the axial Young's moduli of

the two main directions of in-plane deformation and, more importantly, by the shear modulus  $G_d$ . This parameter, depending on the diaphragm thickness, governs the equivalent shear stiffness provided by floor diaphragms to the coupled walls, determining the redistribution of horizontal seismic actions as well. As previously highlighted (§2), the Consoli Palace is mainly characterized by vaulted floors of different typologies. Their geometric characteristics are peculiar, especially those regarding the huge barrel vault covering the Arengo hall, in which narrow and long vaulted rooms have been built within the volume of the vault itself. This complex system of rooms has not been explicitly described in the EF model, coherently with its simplified nature. Nevertheless, the dynamic calibration of the model considers wider uncertainties in the masses and horizontal stiffness contributions provided by this floor (see §4.2).

With similar reasoning and due to its complexity, the roofing system has been modelled only through its mass contribution. It should be remarked that the proper and additional masses of floors, in the EF model, are distributed to the diaphragm perimeter nodes. In the case of the Consoli Palace, these masses are relevant, accounting for 30% of the total mass of the structure.

Another important aspect of the three-dimensional EF assembling regards the degree of connection between walls and horizontal diaphragms and between walls. The first is governed by the stiffness properties of the diaphragms themselves. The second, on the other hand, must reproduce the quality of the anchoring between intersecting walls, depending on the mechanical properties of masonry and the stone arrangement at the walls joint. Different effectiveness of the wall-to-wall connection may be achieved by different modelling strategies in EF models, as discussed in [27], among which the use of connecting beams is particularly effective.

The recent in situ survey (§2) allowed identifying those walls in which the so-called *flange effect* is guaranteed, so to be equivalently described by stiff coupling beams. In other cases, walls are not intersecting but simply leaning against each other, so that the flange effect is negligible. The intermediate cases are reproduced in the model through appropriate connecting beams, whose stiffness properties determine the degree of coupling between intersecting masonry walls.

Figure 5: (a) Finite element (FE) model and (b) Equivalent Frame (EF) model of the Consoli Palace.

Finally, the three-dimensional structure is assembled from bi-dimensional elements, walls elements and floor diaphragms, neglecting their out-of-plane stiffness contributions. This assumption is reasonable and widely adopted in the analysis of ordinary masonry buildings. In the case of Consoli Palace, however, the thicknesses of bearing walls are much larger – sometimes comparable with the in-plane extension, see §2 and Figure 3 – than those found in ordinary buildings. As a consequence, their out-of-plane stiffness is expected to influence significantly the global dynamic behaviour of the structure. This effect has been properly accounted for in the calibration process (see §4.2).

In light of these premises, the resulting three-dimensional EF model (Figure 5b) faithfully reproduces the geometric and structural characteristics of the palace, derived from the available documentation and refined following the on-site investigations. If compared to the FE model (Figure 5a), indeed, the biggest simplification lies in the impossibility to explicitly model the volume of the subsoil at the foundation level. In the EF model, this limitation is overcome by employing proper node constraints.

#### 4.2 Uncertainties and updating technique

The model updating process is formulated as a constrained global optimization problem, in which uncertain mechanical parameters characterizing the structural model are calibrated to minimize the differences between the numerical simulations and the experimental results. Considering the availability of three reliable experimental modes – identified from AVTs in §3.1 and employed for the calibration of the FE model of the palace in §3.2 – resulting in three target frequencies and as many mode shapes, the dimensions of the problem (i.e. the number of free parameters) are limited to a maximum of six unknowns.

The extension of the parameter space, i.e. allowed range of variation of each parameter, reflects (i) the related degree of uncertainty deriving from the limited knowledge of the existing structure and (ii) as thoroughly discussed in the following, some limitations of the EF in modelling such a complex masonry structure (§4.1). Based on this premise, in a preliminary phase, five mechanical parameters – expected to influence the undamped free vibrations of the structure in the investigated range of frequencies – are assumed as the problem unknowns. Their reference values and ranges of variation are synthetically reported in Table 4.

The parameter  $E_m$  represents the masonry Young's modulus of the whole body of the palace. According to the EF idealization, this quantity governs the in-plane flexural response of the vertical structural elements (i.e. piers and spandrels). In this respect, this parameter is expected to have a primary influence on the natural frequencies of the global (in this case, translational and rotational) modes. Since no experimental tests are available to directly characterize the mechanical properties of the palace masonry, the reference elastic modulus is assumed as the average value of the range proposed by the Italian Circular No. 7/2019 [28] for massive stone (Table C8.5.I) – which characterizes most of the palace bearing walls – taking into account the good quality of the mortar joint observed during the in situ surveys (Table C8.5.II). Similarly, concerning the lowest acceptable value, the range of variation is constrained according to the same code provision. Conversely, the less stringent upper bound is mainly aimed at an indirect in-plane compensation of the unmodeled out-of-plane stiffness of the vertical elements (§4.1). This statement should not be surprising, observing the significant out-of-plane thickness of the bearing walls (§2). The in-plane shear contribution, governed by the shear modulus of the masonry  $G_m$ , is derived assuming a Poisson ratio equal to 0.2 – as in the FE calibration (§3.2) – leading to  $G_m = E_m/1.4$ .

Parameter	Description	Reference value	Lower bound	Upper bound
$E_m$ (MPa)	Young's modulus of palace masonry	3420	2400	12000
$E_{mt}$ (MPa)	Young's modulus of bell tower masonry	3420	2400	12000
$\rho_m$ (kg/m <sup>3</sup> )	Mass density of palace masonry	2200	1800	2400
$c_{Md}$	Relative variation of floor masses (Arengo and roof level)	1	0.5	1.5
$c_{Gd}$	Relative variation of floor diaphragms in-plane shear stiffness (vaults)	1	0.5	25
$c_{oop}$	Relative variation of $E_m$ along the $y$ direction	1	0.5	1.5

Table 4: Reference values and variation boundaries of the parameters calibrated in the updating process.

The Young's modulus of bell tower masonry  $E_{mt}$  governs the frequency of the local modes of the bell tower, in particular those involving its flexural behaviour. From the mechanical point of view, no significant differences are expected between the palace and tower masonries – sharing the same typology, see §4.1. Choosing this parameter as a separate variable, nevertheless, allows decoupling the effects of the unmodeled out-of-plane stiffness belonging to the main building from those belonging to the tower itself. This parameter is expected to be overestimated from the updating procedure as well, due to the significant thickness of the pillars supporting the bell tower.

The variation of the mass density  $\rho_m$  of the palace masonry is constrained according to a limited uncertainty related to the building material properties. It should be remarked, in this regard, that the wall mass contribution is around 70% of the total mass of the building, making the calibration process quite sensitive even to small variations of this parameter.

The relative weighting factor  $c_{Md}$  takes into account the uncertainty in the definition of the proper and added masses insisting on the Arengo vault and the roof level. This parameter addresses the vertical loads contribution (i) the complex system of rooms rising above the Arengo vault and of (ii) the roofing, none of which being explicitly described by the model (§4.1). Such masses are estimated to be around 2000 ton each, making up around 60% of the floor masses and 15% of the total mass of the palace. According to the EF modelling assumptions, the diaphragms masses are lumped to the nodes located on the supporting perimeter walls, so that their variation is expected to influence the torsional inertia of the floors.

The coefficient  $c_{Gd}$  allows tuning the equivalent in-plane shear stiffness  $G_d$  provided by horizontal diaphragms, in particular by those representing vaulted floors. This choice is justified by the unusually large dimensions of the Arengo vault (§2), which make analytical estimations – such as those presented in [29] and employed to estimate reference values – less reliable. A recent contribution of the literature allows to quantitatively identify the actual shear stiffness of floor diaphragms from ambient vibration data [30]. Nevertheless, in this specific case, the limited number of sensors and their suboptimal location prevent a successful identification [31]. For these reasons, a finer calibration of this parameter is delegated to the updating process.

Finally, the factor  $c_{oop}$  characterizes the masonry Young's modulus of the bearing walls aligned with the  $y$  axis, according to the expression  $E_{m,y} = c_{oop}E_m$ . This parameter addresses the potential unbalance between the global out-of-plane stiffness provided by each direction. Based on simple geometric considerations, observing the huge thickness and length of the two perimeter walls developing along  $x$ , the out-of-plane contribution is expected to be prominent along  $y$  (i.e.  $c_{oop} > 1$ ).

The simplifying assumptions of the 3Muri EF implementation – discussed in detail in §4.1 – and, more in general, those of the equivalent frame formulation, surely make the modelling of a complex structure such as the Consoli Palace a challenging task. On the other hand, if compared to FE modelling, the synthetic EF formulation ensures much lower computational requirements. Taking advantage of this feature, the inverse updating problem is approached from a *global search* perspective, aimed at the extensive exploration of the parameter space.

In particular, a genetic algorithm is chosen among the several global optimization approaches suitable to carry out the updating process. This metaheuristic search, belonging to the larger class of evolutionary algorithms, mimics the natural selection process relying on biologically inspired operators such as *selection*, *crossover* and *mutation*. The initial population size is set to 200 members, sampled uniformly from the bounded parameter space. *Parents* are selected among the members of each population with the lowest objective values. To ensure diversity, each subsequent generation is composed of (i) ten *elite* members, those with the highest ranking from the previous generation, (ii) 80% of the remaining members generated from parents *crossover* – mixing different *genes*, i.e. parameters – and (iii) 20% generated from parents *mutations* – applying random Gaussian noise to their parameters.

The single objective function  $\Pi$  to be minimized is representative of the relative differences between simulated and experimental modes, according to the expression

$$\Pi = w_f \Pi_f + w_s \Pi_s, \quad w_f + w_s = 1$$

$$\Pi_f = \sum_k \left( \frac{f_{n,k} - f_{e,k}}{f_{e,k}} \right)^2, \quad \Pi_s = \sum_k \frac{(1 - \sqrt{\text{MAC}_{ne,kk}})^2}{\text{MAC}_{ne,kk}} \quad (2)$$

where  $\Pi_f, \Pi_s$  measure respectively the differences in natural *frequencies* and mode *shapes* [32] – whose relative importance is governed by the weighting factors  $w_f, w_s$  – over the  $k$  selected modes. The expressions of  $\Pi_f$  and  $\Pi_s$  are balanced in their relative magnitudes, so that the updating process is penalizing frequency differences when MAC [33] values are greater than 0.7. Based on this consideration, intrinsically addressing the higher robustness of experimentally identified frequencies compared to mode shapes, the weights  $w_f, w_s$  are initially assumed to be both equal to 0.5.

### 4.3 Dynamic calibration based on experimental results

Few are the contributions of the literature addressing the use of AVTs results to dynamically calibrate EF models, aimed at reducing the aforementioned epistemic and aleatory uncertainties intrinsic to the modelling process [34].

Considering the set of experimental modes identified by AVTs (§3.1) and following the approach followed by the FE model calibration (§3.2), the first, second and fifth identified modes (Table 1, Figure 3) are selected as the target of the updating process. Convergence – as an average relative variation in the best objective function lower than 10% – is obtained at the eleventh generation, corresponding to 2300 function evaluations (modal analyses solved with the TreMuri research version [15]). The solution is achieved in around 40 minutes, exploiting the multiprocessing capabilities of a modern quad-core CPU. This time is comparable with the one employed by the corresponding FE model to solve a single modal analysis.

A first calibration is pursued employing a synthetic EF model in which the bell tower is not explicitly modelled, i.e. addressing its inertial contribution only. The corresponding label *w/oT* stands for “*without tower*”. The set of reference parameter, named *w/oT0* (Table 5), produces (i) large underestimates of natural frequencies and (ii) for the second mode, a poor mode shape correlation (Table 6). In particular, the relative frequency differences  $\Delta_f = (f_n - f_e)/f_e$  range

from -30% to -50%. This outcome was expected, given the importance of the unmodeled out-of-plane stiffness of the bearing walls (§4.1). The calibration results (referred to as w/oT1) show that, despite significant improvements in the objective function, frequency differences remain large. Indeed, a better agreement could be achieved – for example, setting  $w_f, w_s$  equal to 0.8 and 0.2 respectively – at the cost of completely losing the mode shape correlation of the second mode. Conversely, no set of parameters manages to improve such a correlation, due to the torsional component not observed in experimental results (Figure 6a).

If the explicit introduction of the bell tower – label  $T$  – does not improve significantly the reference configuration T0, better results are obtained from the calibration of the tower stiffness properties. The calibration T1 achieves (i) frequency differences lower than 5% for the first two modes and lower than 10% for the fifth mode and (ii) good mode shapes accordance, resulting in a reduction of the objective function of one order of magnitude (Table 7). Remarkably, the second mode shows a pure translational behaviour along the  $x$ -direction (Figure 6b), significantly improving the agreement with experimental observations. This outcome seems to confirm the primary role played by the bell tower and its non-negligible influence on the global dynamics of the palace.

The corresponding set of updated parameters, compared with their reference values, shows a large increase in Young's moduli of both the palace and bell tower masonries. In the case of tower's pillars, a simple manual estimation of the unmodeled out-of-plane stiffness – ranging from 1.25 to 1.5 times the corresponding in-plane stiffness for the cantilever and double-clamped schemes – yields physically reasonable estimates of the elastic moduli. The parameters governing the wall and diaphragms masses show a reasonable decrease, compatible with the initial underestimation of natural frequencies. The coefficient governing the in-plane shear stiffness of floor diaphragms, close to its upper bound, suggest the underestimation of the stiffness properties of vaults (§4.2).

Parameter	w/oT0	w/oT1	T0	T1	T2
$E_m$ (MPa)	3420	6450	3420	11960	7650

Table 7: Comparison between the experimental results and the updated EF model T.

Figure 6: Shape of mode 2 in the (a) w/oT1, (b) T1 and (c) T2 updated EF models.

Introducing the coefficient  $c_{oop}$ , accounting for the directional effects of the unmodeled out-of-plane stiffness (see §4.2), does not bring improvements to the updating process. Nevertheless, solution T2 gives some further insights into the model dynamic behaviour. Comparing T2 with T1, neglecting the small variations in mass density, a lower stiffness along the  $x$ -direction allows obtaining equally satisfying results. Conversely, a much higher stiffness along the  $y$ -direction – 1.5 times greater than that of  $x$  – forms the optimal solution, confirming the expectations regarding the unbalance between the out-of-plane contributions provided by each direction.

#### 4.4 Comparison with the updated FE model

The results of the model update process (§4.2) show the ability of the calibrated EF model to correctly reproduce the experimental dynamics of the Consoli Palace. The unusual complexity of the structure, in this case, highlights the limitations introduced by common assumptions in the EF modelling of masonry structures as well. In the following, a detailed dynamic comparison with the updated FE model of the palace (§3.2) gives further insights on the suitability of these two formulations in supporting the SHM of historical masonry structures. Since the update of both structural models targeted the same experimental modes, the comparison is extended to the entire set of the first five modes (regardless of their employment in the updating process). Moreover, to overcome some issues faced with experimental mode shapes – mainly related to spatial aliasing and due to the absence of sensors on the bell tower, §3.1 – the two models are compared accounting for an increased number of nodes.

From a dynamic point of view, the two models show a similar ability to reproduce the ambient behaviour of the palace (see Table 3 and Table 7). Indeed, the FE model does not suffer from critical modelling simplifications (such as those related to the out-of-plane stiffness) which makes the EF updating process less straightforward. For these reasons, rather than looking at the constitutive parameters, it seems more interesting to compare directly the models' dynamic response.

For what concerns the calibration T1, the EF model does not correctly reproduce some modes of the FE model (Table 8), in particular the third mode – involving the flexural behaviour of the bell tower, Figure 3. This result is not unexpected, considering that this mode has not been included in the updating procedure. Undoubtedly, the most important difference between the two models lies in the second natural mode. In the EF model, mode 2 is mainly characterized by a *local* flexural behaviour of the bell tower in the  $x$ -direction. From a seismic point of view, this causes the activation of only a small fraction  $m_x$  of the total dynamic mass. In the FE model, on the other hand, the mode *globally* involves both the main body of the palace and the bell tower, so that a significant portion of the total dynamic mass is activated.

Calibration T2 appears to overcome most of these drawbacks. First, there is a remarkably good agreement in frequencies and an acceptable correlation in mode shapes – even for modes 3 and 4, excluded from the updating. Second, and more importantly, mode 2 configures itself

as a global mode, with a participant mass ratio comparable with the FE one. This finding emphasizes, again, the influence of the bell tower on the global dynamic behaviour of the structure, calling for further experimental investigations specifically aimed at identifying such an interaction.

Mode	FE (26000 ton)		EF – T1 (25800 ton)				EF – T2 (25000 ton)			
	$m_x$	$m_y$	$m_x$	$m_y$	$\Delta_f$	MAC	$m_x$	$m_y$	$\Delta_f$	MAC
1	0	0.80	0	0.57	-0.011	0.98	0	0.58	-0.044	0.98
2	0.52	0	0.05	0	0.003	0.79	0.45	0	0.046	0.73
3	0.10	0.01	0	0.02	-0.105	0.37	0.01	0	-0.031	0.65

## 5 CONCLUSIONS AND FUTURE PERSPECTIVES

The paper proposes an uncommon application of the equivalent frame (EF) technique to the structural modelling of a historical masonry palace, the Consoli Palace of Gubbio, Italy. The EF modelling of such a complex and heterogeneous structure poses some challenging issues, which are discussed and specifically addressed in the work. The computational efficiency of the model allows the employment of a global search updating strategy, aimed at minimizing the differences with the experimental modal properties of the structure identified from ambient vibration tests. The results show the capability of the EF approach in describing the elastic dynamic behaviour of the structure and the need, for this structural typology, to overcome some limitations arising from simplifying modelling assumptions. The most relevant, in this case, proves to be the out-of-plane stiffness of the bearing walls, which is implicitly incorporated by the in-plane stiffness in the calibration process. The good accordance with the refined and updated Finite Element (FE) model of the structure confirms the possibility to employ the simplified EF formulation to support the model-based health monitoring of the palace. The comparison highlights, finally, the primary role played by the bell tower in determining the global dynamics of the structure. This outcome calls for further experimental investigations, which are being addressed within the Italian PRIN 2017 project *DETECT-AGING* through an extended dynamic, static and environmental monitoring system that has been recently deployed. The future developments will tackle the employment of both the EF and FE in the statistical simulations of post-seismic scenarios, supporting the localization and quantification of damage from vibration measurements through *metamodelling*. Further refinements of the EF model, aimed at the explicit description of the out-of-plane stiffness contributions of walls, are currently ongoing.

## 6 ACKNOWLEDGEMENT

This research has been supported by the Italian Ministry of Education, University and Research (MIUR) thanks to the funded project of national interest *DETECT-AGING* – “Degradation Effects on sTructural safEty of Cultural heriTAGE constructions through simulation and health monitorING” (Protocol No. 201747Y73L).

### Abstract

*The development of Machine Learning, which is deemed to be the path to Artificial Intelligence, has changed tremendously the way many computationally intensive tasks are treated nowadays. Regarding the design of R/C columns and bridge piers, the results of a recent project which proposes a number of design functions are examined and discussed in this work. Both rectangular and circular as well as solid and hollow sections are treated. The proposed design functions are naturally immune to numerical instabilities and achieve more than adequate accuracy for design. They are also, by nature, orders of magnitude faster than any design algorithm based on iterative equilibrium procedures. The error estimation for each function is described in detail based on extensive test sets. Certain method pitfalls, which were encountered and successfully treated, are also discussed.*

**Keywords:** Machine Learning; Artificial Neural Networks; Big Data; Reinforced Concrete; Design; Columns; Bridge piers.

---

## 1 INTRODUCTION

Reinforced concrete (R/C) vertical members (e.g., columns, bridge piers, structural walls) are generally subjected to a combined action comprising two perpendicular planes of flexure (biaxial bending) and a usually compressive axial load. The magnitude and ratio between these three actions ( $N$ ,  $M_x$ ,  $M_y$ ) mainly depends on the stiffness and position of the member within the structure and the applied loading combination (e.g., gravity, seismic, wind). The design of critical sections for these vertical members, i.e., the calculation of required reinforcement, is normally carried out either by use of traditional design charts (e.g., [1]) or by more rigorous algorithmic solutions that require modern computational resources (e.g., [2,3]). Numerous repetitions of the above design process are usually required at structural level; therefore, its computational efficiency is of prime importance.

In this paper, a fundamentally different approach to the design of R/C vertical members is suggested; instead of applying design data (e.g., section dimensions, material properties, etc.) and computational rules (e.g., stress integration, section equilibrium, etc.) to produce answers to the design problem (i.e., the required reinforcement), the exact inverse procedure is applied; using a robust section analysis algorithm, an extensive set (tens of millions) of sample solutions to the problem is first compiled. Then, large Artificial Neural Networks (ANNs) are trained to predict the solution, i.e., the required reinforcement. The obvious reward of this approach is that the forward-propagation can be transformed into closed-form design functions which are by orders of magnitude faster than any iterative schemes. They are also immune to any numerical instability issues.

## 2 MACHINE LEARNING

Machine learning (ML) provides the technical background of data mining, i.e., extraction of information from large datasets, focused on predictions based on known data properties [4]. This is not something new; simple regression analyses based on experimental data can be considered to be early ML applications in engineering. However, regarding the R/C design problem investigated herein, such attempts have not gained much recognition due to the limited amount of experimental data, which may lead to overfitting and eventually inaccurate predictions. Contrarily, the proposed approach operates directly on a huge amount of pre-calculated results which are based on structural mechanics principles and Code regulations [e.g., 5]. It is true that the structure of the produced design functions is obscure; yet, when utilized as a black-box, their results are easily verifiable by comparing them to the results of classic iterative computational methods.

The objective of this work is to produce the simplest possible algorithm (function) that yields an acceptable level of accuracy for practical design purposes. In this context, the initial goal for the calculation of mechanical reinforcement ratio ( $\omega$ ) was to produce a maximum absolute error of 0.01, corresponding to an actual reinforcement area error as low as 0.3 % (in a typical R/C column design). Experimentation with various ML implementations showed that only relatively large Artificial Neural Networks (ANNs) have the adequate complexity to address the high nonlinearities inherent in the data. Moreover, data overfitting can be avoided effectively by using extremely large training sets. These training sets were evenly spaced within a standard range of values for each design parameter. Also, additional engineered parameters were applied to assist the learning process. In order to validate of the applied procedure, new testing sets, unknown to the trained ANN, of double the size of their training counterparts were also compiled. The final measure to ensure the robustness of the proposed method was to apply auxiliary ANN-based functions to screen out unreasonable user input that may cause false output due to extrapolation.

### 3 ANN TRAINING & TESTING

For training and testing the ANN-based design functions, extensive sets were pre-calculated using a robust derivative-free algorithm for section analysis under biaxial bending and axial load [3]. Four section types were considered (**R**ectangular / **C**ircular, **S**olid / **H**ollow) using normalized input parameters, similar to traditional design charts [1]. Two notable novelties were the inclusion of the actual concrete cover ( $c$ ) instead of cover ratios and the consideration of uniformly distributed reinforcement along the section perimeter (constant  $A_s$  per unit length – subscript ‘d’), additional to the standard equal amount per side ( $A_s/4$  – subscript ‘e’) for rectangular sections. Fig. 1 shows the considered section parameters for the various section types.

Fig. 1: Section design parameters

Normal strength concrete (C12/15 to C50/60) with parabolic ( $n=2$ ) stress-strain relationship and standard B500C steel grade (no hardening, no strain limit) was considered, according to the provisions of the latest draft of Eurocode 2 (EN1992-1-1 [6]). Typical ranges for section parameters were (i) a normalized axial load ( $v$ ) from  $-0.6$  to  $0.1$  (compression negative), (ii) rectangular section aspect ratios ( $b/h$ ) from  $1.0$  (square) to  $2.0$ , (iii) hollow section width to size ( $t/b$  or  $t/d$ ) from  $0.05$  to  $2.0$ , (iv) concrete cover to section size ratios ( $c/b$  or  $c/d$ ) from  $0.01$  to  $0.15$  and (v) mechanical reinforcement ratios from zero (no reinforcement) to  $0.7$ , which is deemed a sufficient upper limit for practical design purposes. More details on the ANN setup and the compilation of training/testing sets can be found in [6]. Table 1 shows the set sizes (number of instances) that were finally processed in the present ANN implementation.

Solid section	Training	Test	Hollow section	Training	Test
CS	88,394	177,675	CH	176,823	355,385

Table 1: Training/test set sizes

## 4 RESULTS

The training procedure ran for several days on a modern PC with 128 GB of RAM and produced six closed form design functions for the considered section types. All analyses presented herein have been carried out using Python/TensorFlow. Table 2 shows a detailed overview of these functions, together with the ANN configuration (nodes in the input/inner/output layers). Moreover, it includes the mean absolute error (MAE) and the maximum positive and negative errors (MPE/MNE), in terms of calculated mechanical reinforcement ratio ( $\omega$ ), when tested against independent sets of double the training size. It is apparent that in all cases, the maximum error is well below the initial target of  $\omega = 0.01$ .

Section	Function	ANN size	MAE	MPE/MNE

Table 2: Design functions and ANN performance

The above functions are provided in various programming languages (C#, C++, Delphi, Fortran, Java, MATLAB, Python, VB.NET, VBA) in the following GitHub repository:

<https://github.com/rcslab-auth/Project-Omega>

Fig. 2 shows the typical source code of one of these functions, together with a provided spreadsheet that facilitates their use in everyday practice.

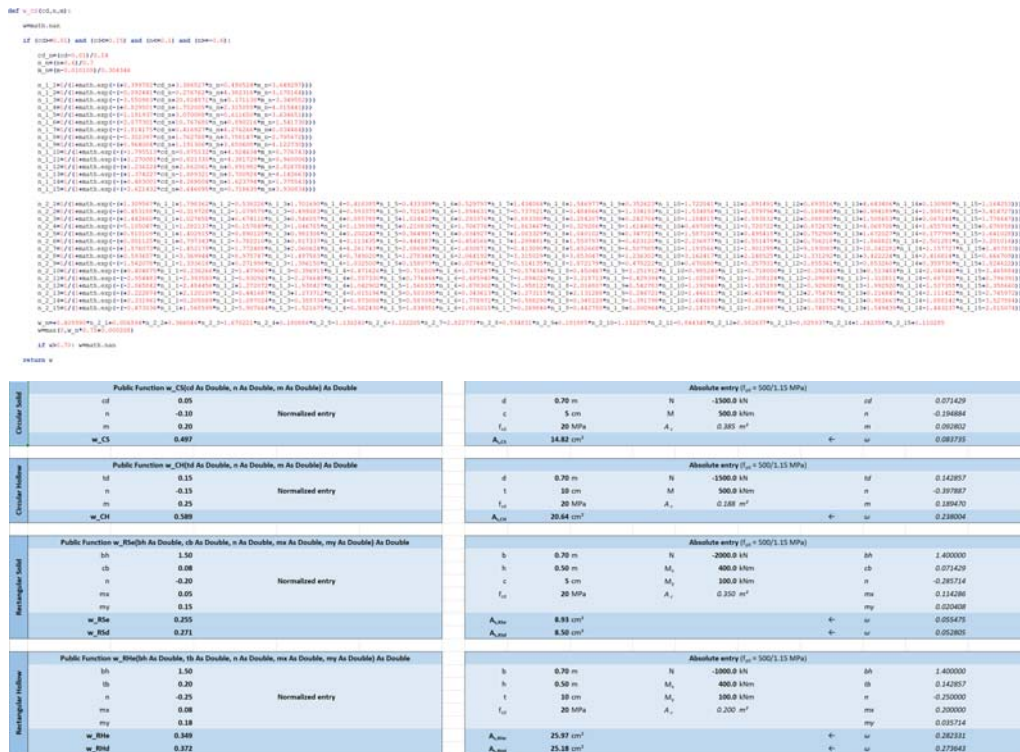

Fig. 2: Function code (Python) and spreadsheet format (Excel)

## 5 ISSUES / VALIDATION / BENCHMARK

In order to prevent invalid user input, all input variables were limited to the aforementioned ranges on which the respective functions were trained for; however, this could not be applied for normalized bending moments ( $\mu_x$ ,  $\mu_y$ ), since their limit values were not known in advance, depending mainly on the axial load level ( $v$ ). This led to unpredictable function behavior for unreasonably high user input for bending moments, which, due to the high nonlinearity of design functions, may wrongly predict values for ( $\omega$ ) in the valid range of  $[0, 0.7]$  (extrapolation issues, Fig. 3a). To remedy this problem, suitable boundary functions were introduced using small ANNs trained on a fixed value of  $\omega = 0.75$ , in order to successfully control invalid user input (Fig. 3b). A detailed description of this procedure can be found in [6].

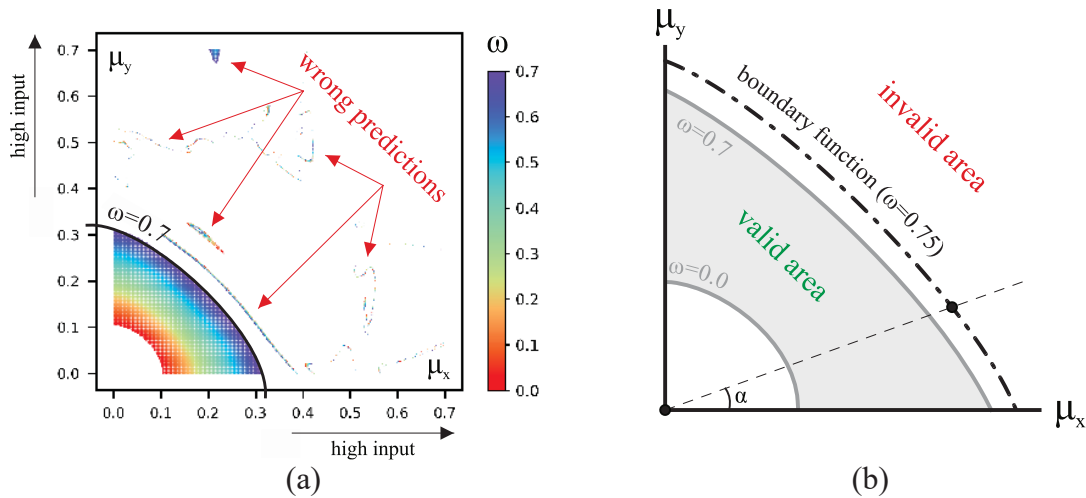

Fig. 3 Extrapolation issues and boundary functions

The accuracy of the suggested design functions was further tested against well-established uniaxial and biaxial design charts [7,1] using millions of moment and axial load combinations that were directly overlaid on charts together with the calculated mechanical reinforcement ratio ( $\omega$ ), as shown in Fig. 4. In all cases, correlation was excellent.

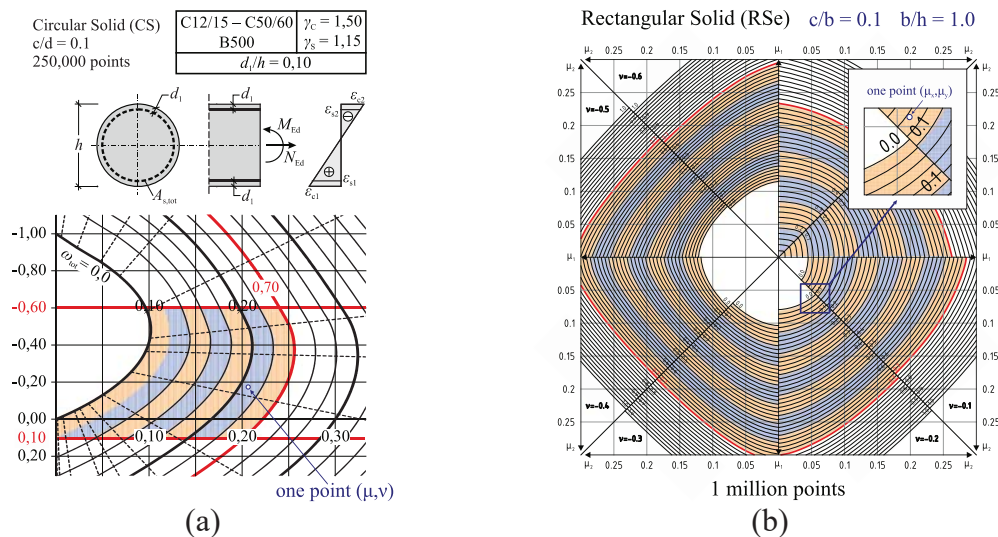

Fig. 4 Design function tests against (a) uniaxial [7] and (b) biaxial design charts [1]

Finally, for evaluating the computational performance of the proposed design functions, one million rectangular solid section configurations were calculated, and execution time was compared against an identical run with a classic fast biaxial design iterative algorithm [8]. It was measured that the execution time for the ML-based functions was about *120 times faster* (5 s compared to 600 s on an average PC). Since the proposed design functions produce closed form (i.e., non-iterative) solutions, it is claimed that these will always outperform by a large margin any iterative design method based on stress integration.

## 6 CONCLUSIONS

In this paper, novel closed-form design functions are proposed for the rapid and accurate design of R/C columns and bridge piers under biaxial bending with axial load, based on relatively large Artificial Neural Networks. The use of these functions outperforms any known iterative design methods by orders of magnitude and it is immune to any numerical instabilities. Moreover, improved features not available in classic design charts, such as constant concrete cover thickness, hollow rectangular sections and constant reinforcement per unit length along the perimeter have been implemented.

All functions are available in a public repository in multiple programming languages, ready to be integrated into design software with minimal effort. It is believed that similar ANN-based regression procedures can effectively substitute traditional programming approaches in many engineering problems, providing the desired accuracy with unprecedented computational performance.

### Abstract

*The fundamental period of a structure is one of the key parameters utilized in the design phase to compute the seismic-resistant forces. Although the importance of seismic-resistant buildings is well understood it has been found that the current design code formulae, which are used to predict the fundamental period of reinforced concrete (RC) buildings are quite simplistic, failing to accurately predict the natural frequency, raising many concerns with regards to their reliability. The primary objective of this research project was to develop a formula that has the ability to compute the fundamental period of an RC structure, while taking into account the soil-structure interaction phenomenon. This was achieved by using a computationally efficient and robust 3D detailed modelling approach for modal analysis obtaining the numerically predicted fundamental period of 475 models, producing a dataset with numerical results. This dataset was then used to train a machine learning algorithm to formulate three fundamental period formulae using a higher-order, nonlinear regression modelling framework. The three newly proposed formulae were evaluated during the validation phase to investigate their performance using 60 new out-of-sample modal results, where, in this work, additional validation models are created and used to test the predictive abilities of the proposed fundamental period formulae. The findings of this research report suggest that the proposed fundamental period formulae exhibit exceptional predictive capabilities for the under-study RC multi-storey buildings, where they outperform all existing de-sign code fundamental period formulae currently in effect.*

## 1 INTRODUCTION

The importance of seismic resistant design of structures and the ability thereof to capture the dynamic response of structures is crucial, especially in areas prone to seismic activity. One of the most important dynamic characteristics is the fundamental period, as it has a significant influence on the calculation of the seismic loads. During a seismic excitation, the interaction between the superstructure (building) and the substructure (soil) can become important as it starts to affect the stress-strain distribution within the superstructure, altering the initial expected results [1-3]. In general, it has been found that soil-structure interaction (SSI) can increase the fundamental period and the overall damping of the system, thus it is important to consider it in order to eliminate unsafe designs and unexpected damage development [4-5] during an earthquake excitation.

Numerous codes worldwide foresee their own methodology of computing the fundamental period of reinforced concrete (RC) structures. However, it is well documented that the current design codes all fail to consider the effect that SSI has on the fundamental period of a structure [3]. There are also some shortfalls with respect to the stiffness distribution of the structure, as the effect of the shear walls is not properly taken into considerations especially in the current Eurocode 8 [6], amongst others as presented in [1]. Thus, establishing design tools that would be able to predict the dynamic properties of RC buildings is of significant importance.

The methodology foresees the use of a computationally efficient and robust 3D modelling technique known as the HYMOD approach [7-9] in order to perform modal analysis to investigate the effect that SSI has on the fundamental period of RC structures. The overall approach foresaw the creation of a dataset comprising out of all the modal analysis results obtained from the various numerical models [1].

Thereafter this research work foresaw [1] the development of fundamental period formulae that were validated through an out-of-plane dataset and were found to have high accuracy. A number of machine learning (ML) and artificial intelligence (AI) algorithms were used to develop predictive models (including closed-form formulae), where it was found that the ability to predict the fundamental period of RC structures through a validation out-of-sample dataset was significantly high. This research work aims to further validate the proposed fundamental period formulae [1] through the use of additional fundamental period results that were developed for the needs of this manuscript.

## 2 MACHINE LEARNING ALGORITHM

The fundamental principles of the ML model are based on the formation of nonlinear terms consisting of various combinations of independent variables, up to the third degree [10]. The algorithm is able to automatically select nonlinear features, corresponding to the minimum prediction error. The data is normalized by subtracting the mean value from it as to eliminate any irregular outliers.

The algorithm was programmed to use 85% of the data to analyse the trends, by identifying relative relationships used to train the algorithm. The remaining 15% of the data is then used to evaluate the proposed fundamental period formulae. The algorithm presented in the next page represents the procedure for the generation of the formula which is developed by the various authors of Julia programming language [11]. Based on the numerical investigation performed for the needs of this work, it was confirmed that the proposed algorithm is efficient providing with the necessary tools in developing the predictive formulae.

### 3 NUMERICAL MODELS AND DATASET DEVELOPMENT

To develop a design formula through training, requires a relatively large number of models that will be analyzed under a modal analysis thereof. The HYMOD approach was used to generate models of RC structures founded on soft, medium and hard soil. This was achieved by extending the work performed by Gravett et al. [7] to add more models to the existing database that was used for the investigation of the SSI effect on RC buildings [1].

The models all originated from the 4-storey RC building studied by Markou et al. [12] with two parallel frames connected by four out-of-plane central beams and a continuous slab of 150mm resulting in a plan area consisting of 3 bays (see Fig. 1). The total span of each parallel frame was 8.9m and had a perpendicular distance of 6.25m between the two frames. Each floor is vertically spaced 3m center-to-center with the central bay infilled with an RC shear wall of 2.9 x 0.25 m section as shown in Fig. 2. It should be noted that the frame of the RC building was designed based on the old Cyprus code [13] and then retrofitted with RC infill shear walls. The reinforcement details for the in-plane beams, columns and shear walls are shown in Fig. 2.

The 475 modal results were generated from models that were modified geometrically, where different soil domains were also assumed. Table 1 shows the minimum and maximum dimensions of the models based on the research work presented in [1]. Fig. 3 shows the case of a 2-storey RC frame with multiple openings, which was then modified to 4, 6, 8 and 10-storey buildings. For more information related to the models' geometries, one may refer to [1].

Figure 3. Double span mesh of a 2-storey RC structure without SSI (a) with shear walls (b) without shear walls.

Variables	Minimum	Maximum
Soil Depth (m)	3	60
Soil E (kPa)	65 000	700 000
H (m)	6	30
L (m)	6.25	18.25
B (m)	6.25	18.25
$\rho$ (%)	0	82.9

Table 1: Minimum and maximum values of the HYMOD meshes.

In order to further investigate the performance of the proposed formulae, a new set of additional validation models were created for the needs of this paper. A diverse set of 15 random models were created which yielded a total of 30 numerically derived fundamental periods. The aim of this validation set was to create random models that have geometries that significantly deviate from the typical geometries used to generate the dataset which was used to extract the proposed formulae.

These models were analyzed by assuming a fixed or flexible base (with and without considering the effect of SSI), which then yielded a total of 15 new models. This was done in order to investigate the proposed formulae to predict the fundamental mode of out-of-sample models since these additional models differ substantially from those in the original validation set [1]. It is important to note that all of the additional validation models fall within the range of values as set out in Table 1. Fig. 4 shows the layout of the five additional validation models, where the model in Figs 4d and 4e foresee the analysis of asymmetric frames in-terms of the shear wall positioning. This type of geometries was not assumed within the dataset that was used to train the models and derive the proposed fundamental period formulae. It is also important to note

here that, the newly developed models foresaw the discretization of a 5m deep soil when the SSI was accounted for, where the soil Young modulus was equal to 300 and 700 MPa. Therefore, 5 fixed models, 5 models with 300 MPa soil and another 5 with 700 MPa soil.

Figure 4. RC building models with soil. (a) 3-storey and (b) 5-storey with a shear wall in the middle, (c) 3-storey shear walls at the perimeter and (d) 2-storey and (e) 3-storey with a single shear wall (asymmetric cases).

#### 4 PROPOSED FUNDAMENTAL PERIOD FORMULAE

Upon successful completion of the ML implementation, three design formulae were generated. The proposed formulae are currently only valid for the range of values shown in Table 1,

as previously discussed. The accuracy of the design formulae is directly related to the correlation between the numerically predicted period and those of the formulae. This in return depends on the number of features used within the design formulae.

Therefore, three individual features were considered (3, 5, and 20) to develop and parametrically investigate the numerical response of the developed formulae. It is important to note herein that the building features that were accounted for, during the training process are the following:

**H** the building's height (m)

**$\rho$**  the percentage of shear walls (%)

**L** the length of building parallel to the oscillating direction (m)

**B** the width of the building perpendicular to the oscillating direction (m)

**$E_s$**  the soils' modulus of elasticity (kPa)

**D** the soil depth (m)

The three different assumptions in terms of the number of features within each formula yielded three different formulae as shown below:

3-Features Formula:

$$T = (0.0332205 \cdot H) - (0.000123101 \cdot \rho \cdot H) + (16.726 \times 10^{-6} \cdot L \cdot B^2) - 0.0275279 \quad (1)$$

5-Features Formula:

$$T = (0.0324913 \cdot H) - (86.048 \times 10^{-6} \cdot \rho \cdot H) + (20.105 \times 10^{-6} \cdot L \cdot B^2) - (28.11 \times 10^{-14} \cdot \rho \cdot L \cdot E_s) - (53.766 \times 10^{-6} \cdot \rho \cdot L) - 0.0173241 \quad (2)$$

20-Features Formula:

$$\begin{aligned} T = & (0.0328677 \cdot H) - (143.475 \times 10^{-6} \cdot \rho \cdot H) - (79.921 \times 10^{-8} \cdot L \cdot B^2) \\ & - (10.458 \times 10^{-14} \cdot \rho \cdot L \cdot E_s) - (55.061 \times 10^{-6} \cdot \rho \cdot L) \\ & - (71.214 \times 10^{-12} \cdot E_s \cdot D^2) + (5.016 \times 10^{-6} \cdot L \cdot H \cdot D) \\ & - (2.93 \times 10^{-18} \cdot B \cdot E_s^2) + (7.121 \times 10^{-10} \cdot B \cdot E_s) + (8.702 \times 10^{-6} \cdot L \cdot H^2) \\ & + (93.621 \times 10^{-8} \cdot L \cdot \rho^2) - (6.093 \times 10^{-6} \cdot L \cdot H \cdot \rho) + (3.351 \times 10^{-6} \cdot \rho \cdot H^2) \\ & + (60.549 \times 10^{-12} \cdot B \cdot E_s \cdot D) + (16.982 \times 10^{-5} \cdot B^2) - (64.89 \times 10^{-6} \cdot H^2) \\ & - (9.776 \times 10^{-12} \cdot H \cdot E_s \cdot D) + (1.477 \times 10^{-17} \cdot H \cdot E_s^2) \\ & - (44.111 \times 10^{-10} \cdot H \cdot E_s) - (2.891 \times 10^{-6} \cdot H \cdot D \cdot B) + 3.8476 \times 10^{-4} \quad (3) \end{aligned}$$

Each formula was compared against the numerical results from the modal analysis in order to evaluate the average absolute error which resulted in 9.04%, 7.86% and 5.35% for the 3-, 5- and 20-feature period formulae, respectively [1]. An additional set of 60 out-of-sample modal results were developed [1], where the proposed formulae managed to predict the results with a high accuracy and outperform any existing fundamental period formula that can be found in the international literature. However, the ability of these formulae to predict out-of-sample cases should be further investigated through the use of more unconventional in-terms of geometry buildings as it is going to be presented in the next section.

## 5 ADDITIONAL VALIDATION RESULTS

Numerically computed periods derived from the additional validation models that were developed herein (30 additional modal results) were compared against those obtained from the formulae for each case. The numerically predicted periods were plotted against those obtained from the formulae for each case along with their correlation as can be seen in Figs 5 – 7.

By evaluating the correlation between the relationships of the numerically calculated periods against those obtained from the formulae for each case, it is easy to observe that a high correlation was achieved for each formula. The relationship obtained from the 20-feature correlation

indicates that the formula yields a very good prediction deriving a prediction error of 8.5% (see Table 2). The 5- and 3-feature formulae have less accuracy given that their complexity and ability to account for the contribution of each feature of the building and its soil is not as high as that of the 20-feature formula. It is also interesting to note at this point that even though the newly developed validation models vary substantially from the original models used to train the formulae [1], the proposed formulae were still able to accurately predict the fundamental periods (Figs 5 – 7) demonstrating their ability to predict out-of-sample results.

Figure 5. Extra validation data. Correlation of the 3-feature formula.

Figure 6. Extra validation data. Correlation of the 5-feature formula.

Figure 7. Extra validation data. Correlation of the 20-feature formula.

Table 2 shows the comparison between the proposed formulae and the design formulae of Eurocode [6] and NEAK [14]. It is easy to observe that the Eurocode 8 formula derives the highest mean absolute error, while the 20-feature formula the lowest, which is a finding further supporting the research findings of [1].

Description	Formula	Mean Absolute Error
3-Feature Formula	Eq. 1	13.0%
5-Feature Formula	Eq. 2	11.4%
20-Feature Formula	Eq. 3	<b>8.5%</b>
NEAK	$T_{NEAK} = 0.09 \frac{H}{\sqrt{L}} \sqrt{\frac{H}{H + \rho L}}$	17.7%
EC 8	$T_{EC} = C_T H^{0.75}$ , with: $C_T = 0.075$	62.0%

Table 2: Fundamental Period Formulae predictions on the additional validation data.

## 6 CONCLUSIONS

The parametric investigation of three newly proposed fundamental period formulae was performed on 30 additional out-of-sample modal results and their ability to predict the fundamental period of RC buildings was performed. The 3-, 5- and 20-feature formulae displayed minimal errors when compared to the validation sets, concluding in very promising results thus verifying the findings reported in [1].

It was also found that the 20-feature formula exhibited a higher overall accuracy due to its high number of features, a finding that is in line with the work presented in [1]. The 3-feature formula had the highest error as it was not able to include the SSI related parameters, where the 5-feature formula was found to provide an improved predictive ability. It was also observed that, even though the out-of-sample models that were used to generate the additional validation modal results were dissimilar to the models used to generate the training dataset in-terms of geometry, the proposed formulae managed to derive good predictions with high accuracy. This highlights the extendibility of the proposed fundamental period formulae.

It is also interesting to note at this point that the 20-feature formula is not “elegant”, consisting of numerous features, but according to the authors’ foresight, this will be the future of Civil Engineering design, where ML and AI-generated models will be directly integrated within software tools that will be used to design our structures. Finally, future work foresees the development of additional models that will extend the spectrum in terms of the geometry of RC buildings, developing new formulae that will be able to predict the fundamental period of structures of various shapes. The case of steel structures will also be investigated in a similar project that is currently active.

### Abstract

*This paper focusses on the ongoing discussion of developing a single relationship that can accurately predict the shear capacity of slender, reinforced concrete (RC) beams without stirrups. To date, the main approach used to predict the shear capacity of RC beams, has been based on the derivation of a formula from experimental data. In this study, the approach uses the development of RC FEM models without stirrups, where the beam width is larger or equal to the section height and tested under three-point bending. The models were created and analysed by using Reconan FEA software, where the obtained results from the nonlinear analyses were used to construct a large database of 10,000 beams with varying material and geometric properties. Artificial Intelligence (AI) training was performed by using machine learning algorithms on the numerically generated database to develop predictive models and to develop an improved formula for predicting the shear capacity of RC beams without stirrups. The proposed predictive formula was validated against an available ACI database of RC beams that were assembled by using experimentally tested, physical beams without stirrups. The predictive formula was also compared with the design code formulae proposed by ACI 318-19 and Eurocode 2. According to the numerical findings of this research work, the proposed formula outperformed both design formulae demonstrating significant potential in replacing the current design approach.*

## 1 INTRODUCTION

Shear failure of Reinforced Concrete (RC) beams takes place due to insufficient shear resistance in the web of the beams. It is important to sufficiently understand the shear capacity of beams in civil engineering applications to avoid catastrophic, brittle failures that occur suddenly, with little to no warning.

The behaviour of RC in shear has been a topic of discussion for numerous years, but the challenge of accurately predicting the shear capacity of RC beams remains an unresolved problem. The main approach so far has been to derive formulae using physical experiments and extrapolating the relevant values. This method is unfavourable, as a major disadvantage is insufficient available experimental data. It is impractical and infeasible to conduct enough physical experiments to cover all possible beam geometries, concrete and steel reinforcement properties, load cases and boundary conditions. The existing formulae are based on a limited number of physical experiments and do not consider other cases, such as the use of deep beams experiencing arc action, or different material types of reinforcement rebars. Therefore, the use of the current design formulae is in need of improvement and expansion.

With the rise of Artificial Intelligence (AI) and Machine Learning (ML) in the past 20 years, researchers and engineers have explored the use of ML algorithms on experimental data sets to predict the shear capacity of beams more accurately. To an extent, this method improved the predictive abilities for certain geometries of RC beams, but the restriction of available experimental data sets still limits the prediction capabilities. These studies were also numerically constrained and the accuracy of predicting the shear capacity of beams is unsatisfactory.

In this research paper, the approach originally introduced by Bakas et al. [1] is extended. Instead of using the results obtained from limited experimental data sets, this newly developed procedure focusses on generating a large numerical database by using Finite Element Method (FEM) software and then using these models to train ML algorithms in order to predict the shear capacity of slender RC beams with no shear reinforcement. The proposed new formula will therefore solely be based on 3D nonlinear Finite Element Analysis (FEA). It is important to note that no physical experiments were used to generate or train the developed formulae. The physical experiments were used for validation purposes only.

This paper aims to more accurately predict the shear capacity of RC beams without stirrups that have smaller geometries, when compared to existing design formulae.

## 2 NUMERICAL INVESTIGATION

A numerical procedure was developed for a database of twenty different geometrical RC beams. The characteristics for each of these beams were then increased by a random generation of 500 material property combinations to produce a database containing 10,000 unique beams. The 3D approach presented in [2-4], was used in the modeling and nonlinear analysis of the beams.

### 2.1 Development of Numerical Campaign

The simply supported, slender, RC beams that were generated for the purpose of this research project used 20-noded isoparametric hexahedral finite elements to model the concrete and the steel plates that act at the supports, as well as 2-noded rod elements for the steel reinforcement bars.

Fig. 1 depicts how the typical generated model looked like. The simply supported, slender RC beam had the smallest mesh of all the constructed beams and spans 1,500 mm. The beam has a 300x150 mm rectangular cross-section that was discretized by using hexahedral elements that are 150x150x75 mm in the x, y and z directions, respectively.

A total of 76 hexahedral elements were used of which 4 were for the steel base plates at the supports, 48 for the concrete hexahedral elements and 24 for the steel reinforcement bars. In Fig. 2 the tensile longitudinal reinforcement bars at the bottom of the beam are embedded rod elements and the applied force at midspan is also visible.

Figure 1. Hexahedral element mesh of a simply supported slender RC beam that has a net span of 1,500 mm and a 300x150 mm cross section.

Figure 2. Embedded rod element mesh of a simply supported RC beam that has a net span of 1,500 mm and a 300x150 mm cross section with loads shown.

The largest mesh that was developed for this research project consisted of 450 hexahedral elements, where 10 elements were used for the steel support plates, 400 for the hexahedral elements and 40 for the steel rebars. The beam has a geometry of 750x350 mm and spans 2,700 mm. The concrete cover for all the beams depended on the height of the section. Beams with a height smaller or equal to 250 mm had a concrete cover of 20 mm and beams with a height larger than 250 mm were modelled to have a concrete cover of 30 mm.

Parameter	Minimum	Maximum
L (mm)	1,500	2,700
b (mm)	300	750
h (mm)	150	350
L/h	6	10.8
h/b	0.33	0.83

Table 1: Minimum and maximum beam geometries used in generating the 20 new models.

Twenty new beam geometries were constructed to generate the database. Only beam geometries where the width is greater or equal to the height were constructed. Table 1 shows a

summary of the constructed models. The first model was generated with the minimum span, height and width values from Table 1 as can be seen in Fig. 1 and the subsequent models were generated by modifying the first model to get the needed geometries and spans. The span values start at a minimum of 1,500 mm and increase with 300 mm up until 2700 mm. Span over section height ( $L/h$ ) and the section height over the width ( $h/b$ ) is also given in Table 1 with minimum and maximum values of 6 and 0.33 as well as 10.8 and 0.83, respectively.

## 2.2 Analysing Multiple Finite Element Beams

To generate a database with sufficient input files, a certain level of automation is needed. Without automation, the required time to generate and analyse the input data would be a major disadvantage. The manual effort required to create the data would reduce the possible scope and negatively impact the resulting benefit of the research project. It was thus important to use automation code for data creation and entry. To minimise the time spent on producing and analysing the various FE models it was advantageous to use the previously developed automation tools from [1], Reconan Multirun v1.00.

A random generation of material properties combinations, consisting of  $f_c$  (kPa),  $E_c$  (kPa),  $f_t$ ,  $\beta$ ,  $E_s$  (kPa),  $f_y$  (kPa) and  $A_s$  ( $m^2$ ), was performed and used to generate the corresponding input file for each individual model. Each model's parameter input file included the node ID that had to be monitored, the direction in which the deflection was monitored, maximum deformation, the beam span as well as the section geometry with section height and section width. In all the generated models the node that was identified for monitoring was chosen as the nodal point at the centre of the total span, at the bottom of the beam's height and in the middle of the width.

The Reconan Multirun software was developed to modify each of the 20 model meshes that were generated to have the required material property assumptions and reinforcement ratios as described herein. The Reconan FEA [5], which was also algorithmically modified to read and analyse these FE input files to return the maximum capacity of the beam as well as the maximum deflection. It must be noted that, Reconan Multirun can also read the generated output files with the purpose of continuing the analyses if it was interrupted. This is a useful feature as unplanned power failures or system interruptions, such as operating system up-dates, would otherwise result in substantial delays and rework.

For each of the 20 models constructed as described in section 2.1, 500 different material properties and reinforcement ratio combinations were used, thus resulting in 10,000 analysis results that were used in training the AI algorithm.

The personal computer (PC) used for this research project had a 12-core i7-8700K CPU @ 3.70 GHz and 64.0 GB RAM and had the capability to run 10 Multirun analyses at the same time. As the model meshes became larger, with a larger span and geometry, the computational time to run the analyses increased. The entire analyses of all 10,000 models completed in roughly 36 hours, highlighting the computational efficiency of Reconan FEA [5] in performing nonlinear analysis using 3D detail models.

## 3 DEVELOPMENT OF THE PROPOSED FORMULA

For the second phase, the data was prepared by selecting, pre-processing and transforming the data to apply ML algorithms. The AI training proceeded by extracting the material features and predicting the shear strength of the beams. ML algorithms learn from data, so it was crucial that the right, quality data is fed into the system. The results achieved by the ML algorithms are directly related to the quality and volume of data used during the training stage.

Data selection for this project entailed generating a database that consisted of ten independent variables, which were split into two groups. The first group involved the variables that were

used during the meshing of the models. These variables included the net span,  $L$  (mm), effective depth,  $d$  (mm) and width,  $b$  (mm). The second group of variables were strength-and material related properties and consisted of: uniaxial compressive strength of a cylindrical specimen ( $f_c$  in MPa), concrete tensile strength ratio ( $f_t$ ), steel yielding stress ( $f_y$  in MPa), Young's modulus of steel ( $E_s$  in MPa), Young's modulus of concrete ( $E_c$  in MPa), remaining shear capacity strength factor ( $\beta$ ) and the tensile longitudinal reinforcement ratio ( $\rho$ ).

The above-mentioned independent variables are presented in Table 2 with the statistical characteristics and minimum and maximum values of the database.

	$L$	$d$	$b$	$f_c$	$f_t$	$f_y$	$E_s$	$E_c$	$\beta$	$\rho$
$\bar{X}$	2100	242	537.5	41	0.061	500.8	200045.8	30024.9	0.034	0.0110
$\sigma$	424.3	59.5	170.2	11.3	0.023	58.5	5602.2	2952.9	0.008	0.0053
Median	2100	230	500	40.9	0.061	499.2	200070.1	30072.1	0.034	0.0111
Minimum	1500	130	300	20.1	0.02	401.2	190000	25000	0.02	0.0016
Maximum	2700	320	750	59.9	0.1	598.5	210000	35000	0.05	0.0199
$c_v$	0.202	0.246	0.317	0.277	0.377	0.1117	0.028	0.098	0.247	0.479

Table 2: Statistical values of independent variables.

### 3.1 Model Training

The training process of any ML algorithm model can be split into 3 major phases: Pre-processing, Feature Selection and Extraction and Prediction.

Pre-processing of the assembled dataset was conducted by normalising the data by dividing each variable in the set by the standard deviation. The normalisation of the dataset was required because the features of the set have different ranges and consists of some outliers. The ranges were however not distorted, and the values of the different variables were changed to fit to a shared scale. Normalisation reduces duplicates in the database and increases the validation accuracy of the model. It also allows the optimization of the ML model to be more robust, as the convergence rate of the gradient descent is reduced.

Feature (or variable) selection then uses a process of dimensionality reduction to decrease the initial set of normalised data to more manageable groups. It greatly improves the ML algorithm's performance and reduces the computational power needed to perform the training. Following on from the feature selection is feature extraction. When a number of features in a dataset become similar or too large, the ML model can suffer from overfitting where the model fits the data too well and is no longer able to fit additional data or predict future observations in a consistent way. Feature extraction is the method for combining certain variables into features, reducing the number of values in the dataset without losing an accurate representation of the original data. The relevance and optimisation of the ML model is also considered during feature selection and extraction.

The algorithm chosen for the prediction phase of the ML and AI process is the NLR (non-linear regression) model. Regression models are used to predict unknown values which are gathered from continuous (regression) variables and the NLR model is consequently beneficial to the research project and produces a closed-form solution. The prediction developed by the NLR model is presented as a formula in section 3.2 of this manuscript.

It is important to note that 85% of the generated database was used to train the algorithm, and the remaining 15% used for testing purposes. The test data proved that the prediction model that was created is accurate. The robustness of the model will be discussed in the next section. In addition, a set of physical RC beams was used for validation purposes, after the testing was performed. This step, which is considered to be the most important, was performed so as to

check whether the proposed formula is able to predict the shear capacity of real beams that were experimentally tested.

### 3.2 Proposed Predictive Equation

The formula developed during this research project, used to predict the ultimate characteristic shear strength  $V_c$ , utilized the NLR ML algorithm and was mainly dependent on  $L$ ,  $d$ ,  $b$ ,  $f_c$  and  $\rho$ . Formulae using 10, 100 and 500 terms were generated and investigated for robustness and accuracy. The higher order NLR that was implemented in this research project consists of a combination of variables that were created up to 3<sup>rd</sup> order. The methodology uses the RF-algorithm (random forests) and the analyses was run on the Julia programming language as written by Dimopoulos and Bakas [6].

During the comparison of the three initially developed formulae, the mean absolute error (MAE) of the ten-term formula was 5.1% higher than the 100 and 500 term formulae, and the MAE for the 100 and 500 term formulae was the same and equal to 6.89%.

The proposed formula to calculate  $V_c$ , was obtained as output from the ML algorithm. The formula with ten-terms and the variables  $L$ ,  $d$ ,  $b$ ,  $f_c$ ,  $f_t$ ,  $\rho$ ,  $\beta$ ,  $E_s$  and corresponding weights are given in Eq. 1. The 10, 100 and 500 term formulae have been validated against the experimental data to determine the most accurate formula.

$$\begin{aligned}
 V_c = & 0.253939 * \rho * d^2 - 0.0571682 * d * L * \rho + 0.0967954 * \rho * b * d \\
 & + 0.0000000193334 * E_s * f_c * d - 0.000000234107 * f_c * L^2 + 0.003624 \\
 & * \rho * L^2 - 0.00809799 * \rho * L * b + 0.00000538644 * f_c * b * d + 343643 \\
 & * \rho * f_t * \beta - 387.761 * \rho^2 * d + 0.950862
 \end{aligned} \tag{1}$$

## 4 VALIDATION OF PROPOSED EQUATION THROUGH EXPERIMENTAL DATA

The validation of the predictive model was conducted using 36 experimentally tested beams that were taken from the ACI database [7] of shear tests on slender reinforced concrete beams without stirrups. The 36 beams were specifically selected to fall within the range of the 20 different beam geometries that were developed for the needs of this research project. The material properties were also within the boundaries of the generated database of the 10,000 models. Any experimental results from the ACI database that had incomplete data, were removed and not included in the validation beams.

It is necessary to mention that the ACI experimental database did not include values for  $f_t$  and  $\beta$ . To include these parameters, the average value of  $f_t$  of the training set was taken.  $\beta$  was chosen as a random percentage of less than 5%. This selection was made to optimise the results from the predictive model and to enhance the performance and accuracy. It is also important to note that all the validation beams were out-of-sample cases, given that the values of material properties and geometrical features differed in comparison to the values adopted for the generation of the 10,000 numerical results.

An additional observation related to the validation data is that, from the 36 beams in the ACI database [7] of experimentally tested beams, there were instances where beams with exactly the same beam geometry, reinforcement ratio and material properties resulted in different ultimate shear capacities. This finding highlights the level of uncertainty when discussing the physically tested beams and confirms that experimental results typically include noise because of uncontrolled factors during the testing phase.

It is noteworthy that the predictive model was successfully constructed without the use of any physical experimental data. By removing the dependency on physical beam data, it was

possible to work with a much larger data set and avoid the inconsistencies inherent in physically collected data. The predictive formula, and the resulting accuracy, is purely based on the results obtained from the FEA. The experimental data used in this section was for validation purposes only.

Two industry-standard formulae were compared with the new proposed model, namely the ACI 318-19 [8] and Eurocode 2 [9]. The data in the experimental data set, with 36 RC beams without stirrups, were used to calculate a predicted shear capacity strength using the industry-standard formulae. The same data were used with the new model and the results were compared against the standard design formulae.

The ACI formula is expressed in imperial units so the data were first converted to the correct metric unit before calculations were made. Eq. 2 is the newly developed ACI 318-19 predictive formula that was published in 2019 and it is more similar to the design code suggested by Eurocode 2 [9]. In the case of this research project, no axial force was present, and  $Nu$  is irrelevant ( $Nu = 0$ ). In the ACI formula, the beam geometry and concrete strength plays an important role. The reinforcement ratio ( $\rho$ ) also has an impact on the shear capacity of the RC beam. The formula in Eurocode 2 (Eq. 3), depends on the reinforcement ratio, strength of concrete and the beam geometry.

$$V_c = \left[ 8\lambda_s \lambda(\rho_w)^{1/3} \sqrt{f'_c} + \frac{N_u}{6A_g} \right] b_w d \quad (2)$$

$$V_{Rk,c} = C_{Rk,c} k (100\rho f_{ck})^{1/3} b_w d \quad (3)$$

$$\text{with } k = 1 + \sqrt{\frac{200}{d}} \leq 2.0 \text{ (d in mm) and } \rho = \frac{A_{sl}}{b_w d}$$

Both formulae were developed based on the results obtained from physically constructing and testing several beams, therefore, they are both semiempirical. The obtained results are graphically displayed in Fig. 3 to 5. In each figure, the physically tested, experimental results are displayed on the horizontal x-axis and the shear capacity at which the beams were predicted to fail, using different formulae and models, is displayed on the vertical y-axis.

Figure 3. Experimental Shear Strength vs ACI 318-19 Prediction.

The influence of the longitudinal reinforcement ratio,  $\rho$ , impacts the outcome of the shear capacity, providing the ACI 318-19 formula with some accuracy. However, the ACI formula

tends to over-predict the ultimate shear capacity of the beams, meaning that a much higher shear strength was calculated than the actual shear strength that the beam could resist.

The accuracy of the Eurocode 2 prediction of the ultimate shear strength of RC beams without stirrups is higher than the ACI formula, with a MAE of 1.1298, thus it is considered more accurate than the 2019 version of the ACI code when implemented on the validation set of beams. From Fig. 4 it is seen that for experimental values of  $V_c$  less than 50 kN, the prediction calculates a much larger value and is less accurate, whereas values of  $V_c$  larger than 50 kN are close to the predicted values.

Fig. 5 compares the experimental shear strength of the RC beams with the new, improved predictive ten-term formula developed by using NLR. When compared to Figs 3 and 4, and looking at the newly calculated MAE, the new ten-term formula is found to be more accurate and best predicts the shear capacity of the beams which fail at a higher ultimate force.

Figure 4. Experimental Shear Strength vs EC 2 Prediction.

Figure 5: Experimental Shear Strength vs NLR prediction formula with ten-terms.

For the new formula the overall distribution of the datapoints is closer to the  $x = y$  line, when compared to the ACI 318 and Eurocode 2 predictions. The proposed predictive formula results look visually similar to those presented in Figs 3 and 4, however, there is a closer and more accurate prediction when looking at ultimate forces smaller than 50 kN.

The forces larger and equal to 50 kN appear slightly less accurate when compared to the Eurocode formula predictions in Fig. 4. The proposed formula yields a more conservative numerical response to the problem by predicting forces smaller than the actual force at which the RC experimental beams fail.

The new 10-, 100- and 500-term formulae were compared by looking at their respective MAEs. The new 10-term formula was the most accurate by far, with a MAE of only 0.4703. Thereafter the 100-term formula with a MAE of 0.6408 and the 500-term formula follows closely with a MAE value of 0.6616. The MAEs of the different predictive models are shown in Table 3, with the lowest error resulting from the new 10-term NLR predictive model generated in this study.

Interestingly, although the model was trained on a dataset with different beams' width-height ratios, it exhibited high accuracy, compared to the Eurocode and ACI building codes. All three of the new NLR formulae composed in this study yield more accurate results than the existing industry-standard design formulae when used to predict the shear capacity of the 36 validation RC beams. The ten-term formula provides the best fit and has the lowest error. Although overfitting is present with both the 100- and 500-term formulae they also provide a lower MAE when compared to the existing industry-standard formulae.

Predictive Model	MAE (%)	Accuracy
10-term NLR	47.03	Best
100-term NLR	64.08	
500-term NLR	66.16	
Eurocode 2	112.98	
ACI318-19	145.51	Worst

Table 3: MAE of predictive models.

## 5 CONCLUSIONS

Non-linear regression algorithms were used to train and test a database that consisted of 10,000 shear strength results. Removing the requirement for physical beam data enabled the creation of a much larger data set, which made it possible to use Machine Learning techniques. The shear strength results from the physical experimental data were only used to validate the results obtained from the combination of the FEA and ML algorithms.

The proposed predictive formula with 10-terms for computing the shear capacity of slender RC beams without stirrups presented in this research project outperformed the existing available design code formulae (ACI 318-19 and Eurocode 2). The new formula was shown to be more accurate and better predicted the shear capacity of RC slender beams without shear reinforcement. FEA used in conjunction with advanced ML was shown to provide a reliable approach in developing a predictive formula for estimating the capacity of RC beams without stirrups.

The proposed predictive formula can be further improved by extending the current generated database with a larger variety of beam geometries, spans, and material properties that fall outside of the current range. Further research can be done on different design codes, such as the Canadian code, and formulae used around the world to compare the accuracy of currently used design formulae.

Furthermore, it is recommended to build on this research by looking at slender beams with shear reinforcement, beams with compressive longitudinal reinforcement bars, deep beams, slabs and RC beams with fibre reinforced polymer rebar as well as RC beams with fibres. Additionally, columns, shear walls and joints should be investigated under monotonic and cyclic loading conditions.

**Keywords:** Seismic Sequence, Neural Networks, Repeated Earthquakes, Structural Damage Prediction, Artificial Intelligence, Intensity Measures

**Abstract.** *Advanced machine learning algorithms, such as neural networks, have the potential to be successfully applied to many areas of system modelling. Several studies have been already conducted on forecasting structural damage due to individual earthquakes, ignoring the influence of seismic sequences, using neural networks. In the present study, an ensemble neural network approach is applied to predict the final structural damage of an 8-storey reinforced concrete frame under real and artificial ground motion sequences. Successive earthquakes consisted of two seismic events are utilised. We considered 16 well-known ground motion intensity measures and the structural damage that occurred by the first earthquake as the features of the machine-learning problem, while the final structural damage was the target. After the first seismic events and after the seismic sequences, both actual values of damage indices are calculated through nonlinear time history analysis. The machine-learning model is trained using the dataset generated from artificial sequences. Finally, the predictive capacity of the fitted neural network is accessed using the natural seismic sequences as a test set.*

## 1 INTRODUCTION

In recent years advanced Machine Learning (ML) algorithms, such as Artificial Neural Networks (ANN), has been successfully applied to many areas of system modelling. Their success is based on the thorough processing of data that captures the behaviour of a system. By detecting patterns in the collected data, valuable information can be extracted and predictions can be made that automate the decision-making process. That fact arrives ML as an advanced tool in modern engineering modelling.

The object of the present research is the application of neural networks to predict the structural damage under seismic sequences. The recent disaster held on March 2021 in Tyrnavos-Elassona region, Thessaly of Greece due to a pair of compatible magnitude ( $M_w=6.3$ ,  $M_w=6.1$ ) [1, 2] shallow earthquakes with more than 1800 damaged or non-serviceable buildings, indicate the critical role of seismic sequences in the final damage state of buildings again. In the field of seismic sequences have been conducted many kinds of research to access the contribution of repeated ground motions on the post-seismic performance state of a building so far, which concluded that aftershocks increase the ductility demands. Amadio et al. [3] studied the influence of repeated shocks on the response of nonlinear Single Degree of Freedom (SDOF) systems using different hysteretic models. Hatzigeorgiou and Beskos [4] conducted an exhausting parametric study on SDOF systems and proposed an empirical relation to calculate inelastic displacement ratio under repeated earthquakes. Hatzigeorgiou and Liolios [5] examined the nonlinear behaviour of Reinforced Concrete (RC) frames subjected to multiple shocks considering a set of eight frames that varied both at height regularity and dimensioning practice. Hatzivassiliou and Hatzigeorgiou [6] studied the accumulation of damage and ductility demands due to seismic sequence on three dimensional RC structures. Hosseinpour and Abdelnaby [7] studied the impact of different aspects, as earthquake direction, aftershock polarity and the influence of the vertical component, on the nonlinear response of RC frames under successive earthquakes. Also, more recently, Kavvadias et al. [8] and Zhou et al. [9] investigated the correlation between aftershock related Intensity Measures (IMs) and final structural damage indices.

Previous several studies have been conducted on forecasting of structural damage due to individual earthquakes, ignoring the influence of seismic sequences. De Latour and Omenzetter [10] investigated the efficiency of ANNs on the prediction of seismic damage on numerous RC frames, Alvanitopoulos et al. [11] also examined regular RC structures and, they incorporate fuzzy layers in ANN configuration (architecture). Later, Morfidis and Kostinakis [12] used feature selection methods in a dataset of 3 dimensional RC buildings to found the more damage correlated set of seismic IMs. More recently, the same authors [13] examined the effectiveness of ANNs on the prediction of damage of non-regular at height structures. Applications of Recurrent Neural Networks (RNNs) on Earthquake Engineering made by González et al. [14] and Mangalathu and Burton [15], also Zhang et al. [16] developed a LSTM (Long-Short Term Memory) network to predict structural response. Convolutional Neural Networks (CNNs) applied by Li et al. [17] and Oh et al. [18] for the same purpose.

In the present study, ANNs are applied, considering real and artificial sequences of double seismic shocks, to predict the amount of final structural damage on an already damaged 8-storey RC frame after a first shock. We use 16 well-known ground motion IMs and the established damage from the first earthquake as the features of the ML problem, while the final structural damage (after sequence) employed as the target. Both damage indices after the first seismic event and after the sequence are calculated through Nonlinear Time History Analysis (NTHA).

## 2 SELECTION OF PRIMITIVE DATA

In this section, the primitive data of the problem is described. Specifically, the selection of the ground motion records and the examined RC frame is presented.

### 2.1 Ground motion records

Both artificial and natural seismic sequences are considered to take into account, the phenomenon of multiple shocks. After the random combination from a suite of 318 acceleration records from several earthquakes, the set of artificial sequences determined. More specifically, every record of the above 318 records suite is combined randomly three times with another record from the same dataset. As a result, 954 pairs of first and second shock are constructed, which are utilised as a training set for the specific ML problem. As a test set, we employed 119 natural pairs of sequential shocks, which occurred from 1972 to 2020. The training and test sets are completely independent with no common record. Both sequential and individual records are selected and downloaded from ESM [19] and PEER NGA West [20] databases. The criteria according to the selection of natural sequences conducted are the time gap between the occurrences of successive shocks which are considered smaller than three months and that the sequential events are recorded by the same station. As a result of this process collected 119 pairs of successive ground motion acceleration records from 41 real seismic sequences, recorded by 65 stations. The occurrences time and Peak Ground Acceleration (PGA) data of the natural sequences listed in Table 1. Every pair concatenated in the same array to compose the sequential ground acceleration time history. In addition, an intermediate zero ceasing time gap of 20 seconds added to eliminate the overlap between the building oscillations due to successive earthquakes. This process is implemented in Python [21], and the new files containing the seismic sequence acceleration signals are exported.

### 2.2 Reinforced concrete structure

Existing buildings designed and constructed without earthquake provisions comprise the majority of structures both in Greece and worldwide, which causes particular concern about their response to a potential earthquake. As an example, in this study we examined an 8-storey planar regular RC frame (Figure 1) designed only for gravity loads by Hatzigeorgiou and Liolios [5], with mean compressive strength of concrete equal to 28 MPa and steel grade S500s. The finite element simulation of the frame held in IDARC 2D [22], using spread plasticity concept and three-parameter Park hysteretic model [23]. Every floor considered to have only one horizontal degree of freedom to into account the huge plane stiffness of RC slab as a rigid diaphragm. Sparsely placed stirrups with poor anchor details are assumed in order to be in accordance with obsolete design codes. Thus, a nonlinear deformation-stress model for concrete without confinement is adopted. As a result, the corresponding concrete curve defined by the initial modulus of elasticity ( $E_0 = 31.42 \text{ GPa}$ ), the strain at the maximum stress ( $\epsilon_{c0} = 2\text{‰}$ ), the ultimate strain in compression ( $\epsilon_{cu} = 3.5\text{‰}$ ), the stress at tension cracking  $\sigma_t = 0.0022 \text{ GPa}$ , and the slope of the post-peak falling branch ( $E_{fb} = -6.2 \text{ GPa}$ ). Also, the bilinear curve with hardening employed for steel with yield and ultimate strengths equal to 550 MPa and 660 MPa respectively and the corresponding strains equal to 2.75‰ and 45‰, according to Eurocode-2 [24] provisions. The initial elastic fundamental period of the structure is equal to 1.27 seconds.

### 2.3 Technicalities

The generation of IDARC 2D input files and the extraction of responses from output files implemented through GNU Octave [25, 26] code. Using the same high-level programming language we automated the multiple analysis process and computed the IMs, which are described in the next section, for the overall dataset of first and second seismic shocks.

Table 1: Seismic Metadata for Natural Sequences (Test Set).

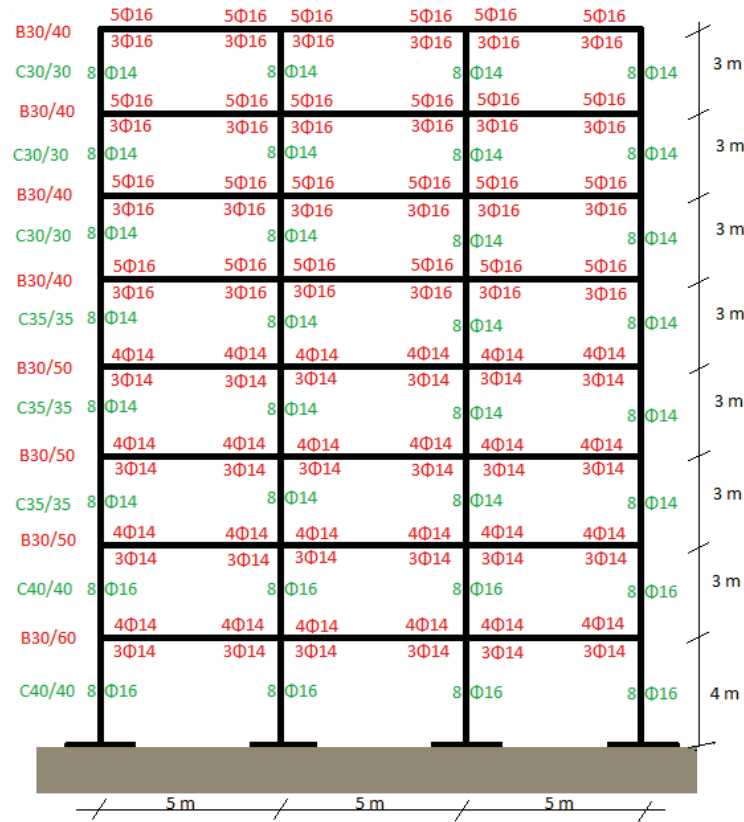

Figure 1: Reinforced Concrete Frame designed by Hatzigeorgiou and Liolios [5].

### 3 FEATURES AND TARGET OF THE ML PROBLEM

This work examined a reinforced concrete planar frame subjected to both artificial and natural sequential acceleration records. The ground motion intensity is evaluated, through scalar measures which are proposed in the literature. The structural damage is accessed in terms of well-known overall damage indices. These features are presented and explained below.

#### 3.1 Ground motion IMs

As previous studies in the prediction of seismic damage amount, we use as features well-known ground motion IMs. The simplest of these are the maximum absolute values of ground accelerations ( $a_g(t)$ ), velocities ( $v_g(t)$ ), and displacements ( $d_g(t)$ ) signals, which referenced as PGA, PGV, and PGD [27], respectively. Widely used IMs are the Intensity Arias ( $I_A$ ) [28] and the Cumulative Absolute Velocity (CAV) [29]. Based on the evolution of Intensity Arias over time the Husid Diagram ( $H_d$ ) [30] is constructed from which duration parameters calculated.

An inherent feature of signals is the frequency content which varies dynamically against the time in the case of ground motion records. However, it is often quantified using the equivalent frequency  $PGA/PGV$  [27] as if it was a sinusoid signal. Another quantity that has been proposed and related to the frequency is the Potential Destructiveness Measure after Araya and Saragoni ( $I_{AS}$ ) [31], resulting from the zero crossings number of the acceleration signal ( $u_o$ ) per unit of time.

Various definitions have been given in the past for the strong motion duration of a seismic excitation, in order to identify the time interval of the signal in which the vast amount of its total intensity is released. In this work, the strong motion durations defined by Trifunac and

Table 3: Descriptive Statistics of 2nd Seismic Shock IMs (Train Set-837 examples).

Brady ( $SMD_{TB}$ ) [32], and by Reinoso, Ordaz and Guerrero ( $SMD_{ROG}$ ) [33] are assumed. Both of these are based on the time evolution of Arias Intensity according to Husid Diagram. Also, the bracketed duration as described by Bolt ( $SMD_{Bolt}$ ) [34], which is defined by the first and last exceedance of the 5 percent of  $g$ , is employed.

Combining the above parameters results in more complex measures such as Power  $P_{90}$  [27],  $a_{rms}$  [27], Characteristic Intensity ( $I_c$ ) [27], the potential damage measure according to Fajfar, Vidic and Fischinger ( $I_{FVF}$ ) [35] and the IM after Riddell and Garcia ( $I_{RG}$ ) [36].

Also, we did not use seismic parameters that depend on the fundamental period, like individual spectral values of the structure due to the elongation of the initial elastic period before the start of the second seismic event. Instead, we employed Housner Intensity [37] ( $SI_H$ ) which accumulate spectral pseudo-velocities to a constant range of possible eigenperiods and presents a high correlation with the structural damage [38, 12, 39]. The calculation of spectrums for the above purpose implemented using OpenSeismoMatlab [40].

All of the mathematical expressions for employed IMs summarised in Table 2. Tables 3 and 4 present the descriptive statistics of the IMs corresponding to the second seismic shocks of the training and test datasets, respectively. We observed that the training set covers the major range of the test set values. From the initially 954 artificially generated sequences, finally we hold 837 of them, which the NTHAs did not present convergence problems.

### 3.2 Damage indicators

In the present section, the damage indices considered in this study are described. The structural damage is used both as an input feature to take into account the existing damage due to the first seismic shock and as a target of the ML problem to describe the accumulated damage after the occurrence of the second earthquake.

#### 3.2.1 Damage index after Park and Ang ( $DI_{PA}$ )

The damage index, proposed by Park and Ang [41], results from summing the contributions of the maximum flexural responses and the hysteretic energy consumed in the plastic hinges areas and is calculated by Equation (1) modified by Kunnath et al. (Equation (2)) [42]. The total damage index [22] is calculated as a weighted average of the sub-factors, weighted by the percentages of the total energy consumed by each member of the construction, according to Equation (3). The overall damage index  $DI_{G,PA}$  as close to zero as possible implies a complete damage-free structural system with an elastic response but when tends to unit characterises a near collapse structure. For abbreviation reason in the next sections  $DI_{G,PA}$  referred to simple as  $DI_{PA}$ .

$$DI_{PA} = \frac{\delta_m}{\delta_u} + \frac{\beta}{Q_y \delta_u} \int dE \quad (1)$$

$$DI_{PA,component} = \frac{\theta_m - \theta_r}{\theta_u - \theta_r} + \frac{\beta}{\theta_u M_y} E_h \quad (2)$$

$$DI_{G,PA} = \frac{\sum E_i DI_{PA,component}}{\sum E_i} \quad (3)$$

where  $\delta_m$  is the maximum element displacement response,  $\delta_u$  is the ultimate element displacement,  $\beta$  is the model constant parameter for strength deterioration proposed by Park et al. [43],  $\int dE$  is the cumulative hysteretic energy consumed by the element during its response,  $Q_y$  is the yield strength of the element,  $\theta_m$  is the maximum element rotation during the time history response,  $\theta_u$  is the ultimate capacity of the element,  $\theta_r$  is the recoverable element rotation during unloading.

### 3.2.2 Damage index after DiPasquale and Cakmak ( $DI_{DC}$ )

During high-intensity seismic events, it is known that the cross-sections in plastic hinges areas of a building can be severely cracked or even present steel yielding, resulting in a stiffness reduction and consequently degradation of the overall stiffness of the structure. Therefore, it is expected that the building will become more flexible and its fundamental period increase. On the above mentioned increasing of the fundamental period due to inelastic dynamic response of a building, based the DiPasquale and Cakmak [44] damage index, calculated according to (4):

$$DI_{DC} = 1 - \frac{T_{0_{initial}}}{T_{0_{equivalent}}} \quad (4)$$

$T_{0_{initial}}$  : The fundamental period before the starting of analysis.

$T_{0_{equivalent}}$  : The fundamental period at the end of the analysis.

### 3.2.3 Max Inter-Storey Drift Ratio (MIDR)

The Max Inter-Storey Drift Ratio [45] during the seismic response of the construction can be used as a measure of the performance it has shown against the earthquake it has hit. The increase in the relative displacements results in an increase of the required floor ductility with similar effects for the rotation and curvature ductility in the areas of the plastic hinges of each component and their cross-sections respectively. So estimating the magnitude of generalised displacements such as MIDR can indirectly aggregate local damages and quantify the total degree of structural damage define by (5).

$$MIDR = \frac{|u|_{max}}{h} 100\% \quad (5)$$

$|u|_{max}$ : Max absolute interstorey deformation recorded during the time history response

$h$ : Storey height

### 3.2.4 Residual Max Inter-Storey Drift Ratio (RMIDR)

Residual displacements cause an important role in the post-seismic performance state of a building to indicate the established damage. Also, consist a critical variable for the reparability of seismic damaged structures [45]. We included it in the problem and evaluate it as the residual maximum inter-storey drift ratio in the post-seismic state, after the end of building oscillation.

## 4 APPLICATION OF NEURAL NETWORKS

The most conventional used Neural Network configuration is the Multi-Layer Perceptron (MLP) [46], which is considered as the simpler learning architecture, consisted from of a few linear layers which are interconnected successively. Each of them receive input from the previous layer, which is multiplied matricially by appropriate weights, subsequently a vector of biases is added. Finally, in every element of the previously defined vector, a nonlinear function is applied to produce the activations of the following layer. This forward process continues until the regression is completed by concluding with the target value from the output layer. The final output values are compared with the real ones, and the regression error is calculated using an

appropriate loss function. The weights of all layers are updated one by one using Stochastic Gradient Descent to minimise the cost function. Data scientists, based on their assumptions and experience, tune their numerous parameters by relating them to the specific problems they need to solve, making use of the available training datasets. Thus, the application of MLP to realistic problems is still challenging and specialised for each problem.

#### 4.1 Gaussian kernel functions

Since the problem under consideration essentially involves the prediction of values based on similar training data samples, kernel function modelling was chosen, which is an appropriate solution as it allows for accurate modelling of data with complex dependencies between input features and target data. They are essentially representations of the input vectors  $x$  in  $\mathfrak{R}$ , which have specific form and properties and are highly generalisable. The appropriate transformation of the input vectors in order to achieve a more easily generalisable solution to the regression problem first requires the transformation of the input space into a transformed feature space with a higher dimension and with a nonlinear representation. The transfer of the problem in a higher dimensional feature space is achieved by the kernel method. In this work, the Gaussian Radial Basis Function kernel (GRBFk) was used, which is appropriate in cases where the identification or manipulation of real values, which tend to cluster around an average value, is required.

#### 4.2 Extreme learning machines

In this paper, a holistic Single-hidden Layer Feed Forward Network (ShLFFN) shallow architecture approach with  $N$  neurons in the hidden layer, randomly chosen input weights and random values of bias constants on the hidden layer neurons, while the output weights are computed by a single matrix multiplication, which automates and optimally solves the problem, was used. These ShLFFN architectures, called Extreme Learning Machines (ELMs) [47], used in complex problems, due to their ability to access any continuous function. Also, the networks in question can learn  $N$  samples with accuracy, while their learning speed can be even thousands of times faster than conventional Feed Forward Network Networks, as their training is not based on time-consuming repetitive processes such as the algorithm. Back Propagation, which changes the weights of the neural network by estimating the quadratic error between the target vectors and the actual network outputs, for all training samples, which are entered into the network in a random serial manner and for many repetitions (epochs)

Driven by the observation that the first stage of the algorithm can be considered as a process of mapping the training vectors into a higher dimensional vector space, in the hidden layer we chose a sufficiently large number of neurons (at least twice the input parameters) so that the algorithm has the property of a universal approximator and can train ShLFFN efficiently. More specifically, the input data are mapped to a random  $\tilde{N}$ -dimensional space with a discrete training set  $N$  where  $(x_i, t_i)$  with  $i \in [1, N]$   $x_i \in \mathfrak{R}^d$  and  $t_i \in \mathfrak{R}^c$ . The output of the network presented in Equation (6).

$$f_L(x) = \sum_{i=1}^{\tilde{N}} \beta_i h_i(x) = \mathbf{h}(x)\beta, \quad i \in [i, N] \quad (6)$$

where  $\beta = [\beta_1, \dots, \beta_{\tilde{N}}]^T$  is the weight matrix between hidden and output neurons  $h(x) = [g(x_1), \dots, g(x_2)]$  is the output of hidden neurons for the input  $x$ , and  $g(x_i)$  is the output of  $i^{th}$  hidden node. Based on  $N$  length training set  $\{(x_i, t_i)\}_{i=1}^N$ , the ELM can solve the learning problem  $\mathbf{H}\beta = \mathbf{T}$ , where  $\mathbf{T} = [t_1, \dots, t_N]^T$  are the target labels and the output matrix of the hidden layer

output presented in Equation (7).

$$\mathbf{H}(\mathbf{W}, \mathbf{b}, \mathbf{X}) = \begin{bmatrix} g(\mathbf{w}_1 \cdot \mathbf{x}_1 + b_1) & \cdots & g(\mathbf{w}_{\tilde{N}} \cdot \mathbf{x}_1 + b_{\tilde{N}}) \\ \vdots & \ddots & \vdots \\ g(\mathbf{w}_1 \cdot \mathbf{x}_N + b_1) & \cdots & g(\mathbf{w}_{\tilde{N}} \cdot \mathbf{x}_N + b_{\tilde{N}}) \end{bmatrix}_{N \times \tilde{N}} \quad (7)$$

Before the training, the weight matrix  $\mathbf{W}$  and the bias vectors  $\mathbf{b}$  initialised randomly in the interval  $[-1, 1]$ , given  $\mathbf{w}_j = [w_{j1}, w_{j2}, \dots, w_{jm}]^T$  and  $\beta_j = [\beta_{j1}, \beta_{j2}, \dots, \beta_{jm}]^T$ . The output weight matrix of the hidden layer  $\mathbf{H}$  came up from Equation (8), given the training data and the activation function  $g$ .

$$\mathbf{H} = g(\mathbf{W}\mathbf{x} + \mathbf{b}) \quad (8)$$

The hidden layer (Figure 2) is responsible for transforming the input data into a different representation. The transformation is achieved in two steps:

- First Step. The input data is input to the hidden layer using the weights and corresponding values of the input layer.
- Second Step. The data is transformed based on a nonlinear transformation function.

Finally, the output weights  $\beta$  could compute from Equation (9).

$$\beta = \mathbf{H}^* \mathbf{T} \quad (9)$$

where  $\mathbf{H}^*$  is the Moore-Penrose generalised inverse matrix for  $\mathbf{H}$ .

### 4.3 Bootstrap sampling and ensemble technique

Bootstrap sampling [48] is adopted so that different subsets of the dataset can train the model in the most fruitful way, to increase the efficiency of the method. Bootstrap sampling is the process of applying progressively larger random samples until the accuracy of the neural network is improved. Every sample is used to train an individual model and the results of each model are summarised by “voting”, i.e. for any input vector, each classifier predicts the output variable and finally, for every variable the value with the most “votes” is chosen. This methodology, which belongs to the Ensemble methods, is called Bagging and has many advantages, such as reducing covariance. The Ensemble technique [49] is used due to the fact that in the specific problem, the prediction results show multivariability, which can be attributed to the sensitivity of the correlation models to the data and the complex relationship that describes them. Also, an important advantage gained by the proposed system is focused on the fact that it offers more efficient and stable prediction model, since the overall behaviour of multiple MLP ANNs is less noisy than a single one, and in any case reduces the overall risk of a particularly inaccurate values. Finally, in order to evaluate the reliability of the implemented bagging method, the variance of the expected error is checked to be around the mean error value.

## 5 RESULTS

This section presents both the results from NTHAs in terms of overall seismic damage indices and the neural network testing in terms of correlations between real and predicted values. In the case of structural damage indices we present both the results of the first shocks NTHAs adopted between the inputs of the ML problem (Figure 2) and the corresponding after the second shocks which employed as targets of the problem.

Figure 2: An ELM neural network architecture uses as input arguments both damage index from the first seismic event and the IMs of the second event to predict the final damage index (after second event).

### 5.1 Results of NTHAs

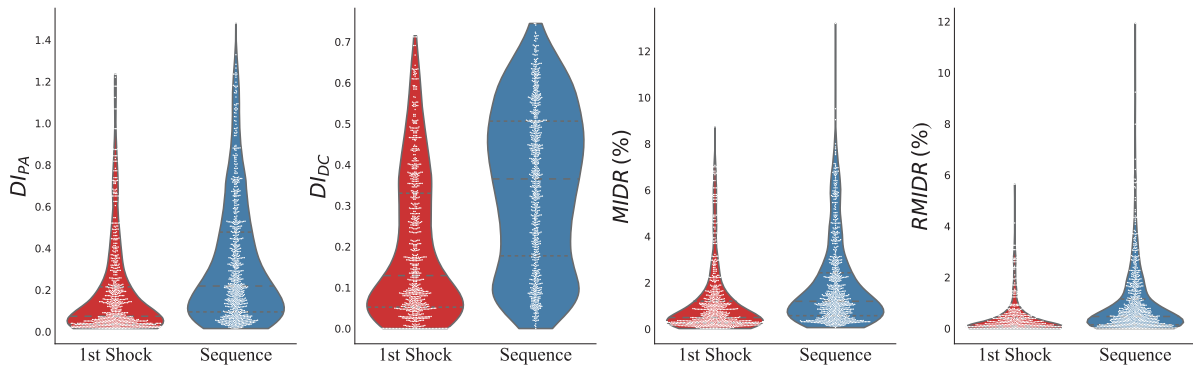

The results of NTHAs represented in terms of damage indices after the occurrence of the first shocks and after the sequences (Figure 3). As we compare the distributions of damage indices after the first and second shock, we see a clear increase after the second shock, both in the training and test set. The increase is higher in the case of  $DI_{DC}$ . The maximum value of this damage index seems to be constant around 0.7 both in the training and test set. The other damage indices have a smaller increase but a clear offset of the upper-end value both to training and test set as we shown in Figures 3a and 3b respectively.

### 5.2 Results of ANN testing

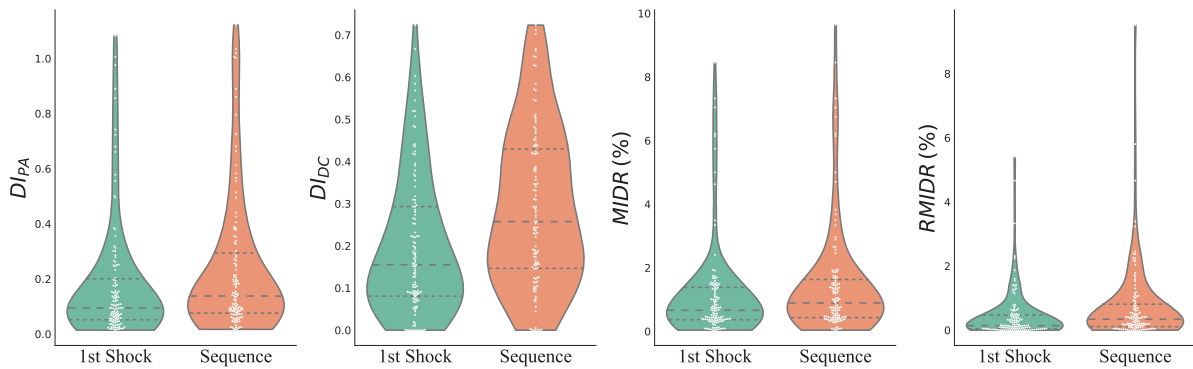

Since the model described in Section 4, trained using the dataset generated from artificial sequences, several correlation coefficients calculated between predicted and actual values of the targets on the test set (natural sequences) to evaluate the effectiveness of the fitted ML model. The results of three correlation coefficients (Pearson, Kendall and Spearman) and two error metrics, Mean Absolute Error (MAE) and Root Mean Square Error (RMSE), for the final fitted model are presented in Table 5. We can observe that the damage indices with the best predictive behaviour are the  $MIDR$  and  $DI_{PA}$  which display the higher values of Pearson, Kendall and Spearman coefficients. The relation between predicted and the actual values of  $DI_{DC}$  looks to be quite linear since the values of Pearson and Spearman coefficients are similar and quite high.

	Pearson	Kendall	Spearman	MAE	RMSE
$DI_{PA}$	0.9104	0.7956	0.9366	0.0574	0.1059
$DI_{DC}$	0.8875	0.7140	0.8898	0.0648	0.0867
$MIDR$	0.8960	0.8277	0.9582	0.3542	0.7933
$RMIDR$	0.8316	0.7488	0.9146	0.2956	0.6870

## 6 CONCLUSIONS

In the present study, we used an ensemble neural network methodology to predict the final damage of an 8-storey RC frame under successive earthquakes. For this purpose, we employed a training dataset of 837 artificial seismic sequences and a test set of 119 natural seismic sequences. Finally, the main conclusions are summarised as follows:

- In both training and test sets, the structural damage under the sequences is increased in comparison with the corresponding damage that occurred after the initial shocks.
- In general, the predictive capacity of the configured Ensemble Neural Network seems to be quite satisfactory.
- The Ensemble Neural Network presents a higher performance in forecasting the final structural damage in terms of  $DI_{PA}$  (damage index after Park-Ang) and  $MIDR$  (Maximum Inter-storey Drift Ratio).

For future machine learning applications in structural damage prediction due to successive earthquakes enriched dataset of natural seismic sequences may be considered. Moreover, a wide range of structural systems should be examined in order to incorporate structural attributes as ML problem input features.

### Abstract

*Seismic risk is one of the main problems in highly urbanized countries with a considerable seismic hazard like Italy. To assess seismic risk of the built heritage, it is necessary to deepen the knowledge of its components, vulnerability in particular. Vulnerability can be evaluated through mechanical methods, which require detailed information on parameters that may affect the seismic response. The implementation of such methods often results in time-consuming and expensive investigations, thus making the risk assessment analysis very cumbersome.*

*In order to make this process easier and faster, remote sensing algorithms can be taken into consideration. In this work, satellite images of areas of interest are automatically extracted via open source online maps, as well as some preliminary information about the buildings detected in the pictures. Afterwards, a filter is set in order to visualize only targeted building typologies (e.g., residential buildings), and street view images are obtained for each selected building. The images are then processed through feature extraction techniques, in order to predict the number of stories of the buildings.*

*The remote and automated retrieval of this feature, along with other meaningful parameters, could allow the association of a specific vulnerability level for each building, thus making on-site surveys unnecessary, with a remarkable reduction in time and costs.*

## 1 INTRODUCTION

Seismic risk is one of the main problems in highly urbanized countries with a considerable seismic hazard like Italy. Even more, seismic risk mitigation represents a major challenge to reduce socio-economic impact of future earthquakes. To carry out seismic risk assessments, it is necessary to deepen the knowledge of the different components of this risk.

Seismic risk is defined as the combination of seismic hazard (probability that a particular earthquake occurs), exposure (number of people, quantity and value of buildings and goods) and seismic vulnerability. The latter can be described as the propensity of a building to suffer a certain level of damage after a seismic event. [1]

In order to assess seismic vulnerability of buildings, it can be useful to define fragility curves, which correlate ground motion with the damage suffered by the buildings. In literature, many approaches allow the calibration of fragility curves. Among others, analytical-mechanical approaches define fragility based on structural models in order to simulate the seismic behavior of buildings. [2-6]. However, when implementing mechanical methods to properly characterize the behavior of buildings at a territorial scale, it is always necessary to collect a big amount of structural data, such as material, construction period, height, as well as some more detailed geometric features. Especially when dealing with large districts or even entire towns, the investigation of these essential parameters often results in time-consuming and expensive surveys, making the risk assessment analysis very cumbersome [7-8].

In order to make this investigation process faster and easier, artificial intelligence techniques may be taken into consideration. For example, instance classification methods have already been used to classify buildings and some of their features using street view images [9-10]. Further information such as building age and category has also been obtained by analyzing morphology, neighborhood characteristics and urban patterns from topographic maps [11-16]. Some works have employed shadow detection techniques in satellite images, in order to estimate building heights [17-19], while others combine maps and street level images to perform the same task [20-23]. In general, it has become evident how artificial intelligence can be useful for elaborating models that extract building information, and consequently for carrying out risk management assessments [24].

In this paper, particular attention is paid to the retrieval of building footprints from satellite images of areas of different sizes, as well as some preliminary geometric and typological features. Subsequently, a methodology for estimating building heights (in terms of number of stories) from street view images is presented, where image processing and feature extraction techniques are used. The main steps of the algorithm are commented, along with the resolution of the main obstacles that can be encountered when analyzing street view pictures.

## 2 AUTOMATED RETRIEVAL OF BUILDING FOOTPRINTS

When seismic risk analyses are to be carried out at a territorial scale, an important element to assess is building exposure. This first step is necessary to understand how urbanized the area is (how many buildings there are), as well as to identify the building typologies. A good estimate of exposure, indeed, takes into account the different usages of buildings, as well as their construction material, construction period, etc.

For this aim, a Python code was developed, in order to retrieve building footprints given a specific satellite image.

To retrieve the desired satellite image, the script provides two input possibilities: the user can search a place by town/municipality, or can enter a pair of coordinates (latitude and longitude) and distance radius  $R$ . In the first case, the program will also return the centroid of the chosen town (in terms of latitude and longitude); in the second case, the program will extract

the name of the municipality, region and country to which the chosen area belongs. The code performs this task through the Static Maps service from the Mapbox API. Figure 1 shows two example of satellite images: Figure 1a shows an image extracted for an entire town (Padova), while Figure 1b displays an area centered in the point (45.409605, 11.888727) with a radius  $R$  of 300 meters.

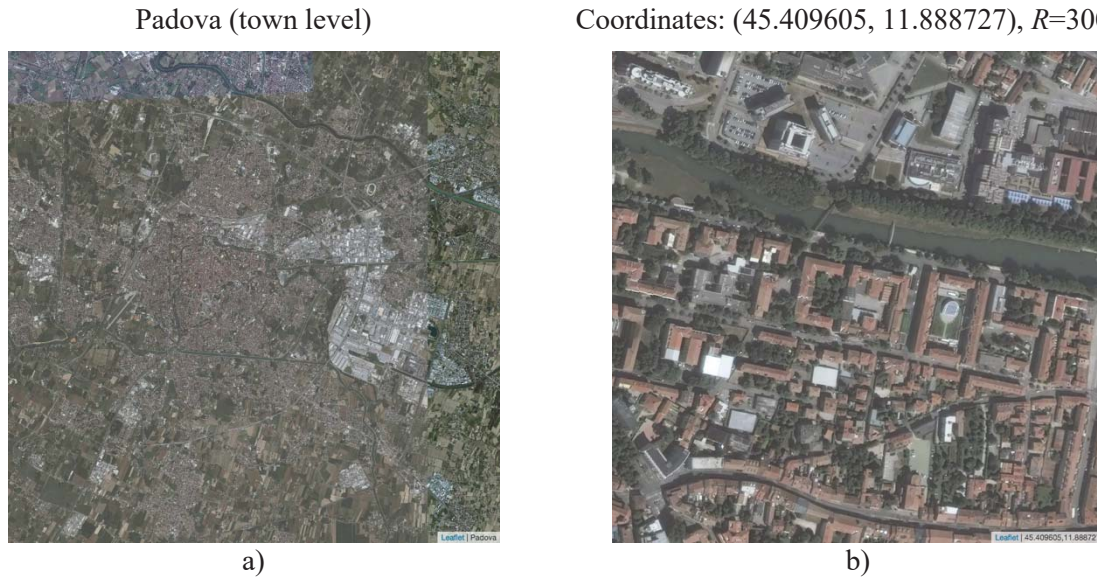

Figure 1: Satellite images for a) the town of Padova, b) an area centered in the point of coordinates (45.409605, 11.888727) with a radius of 300 meters

The second step of the code involves the acquisition of the building footprints that can be found in the satellite images. To do so, the OSM dependency is utilized, which provides access to OpenStreetMap services. Particularly, the key “building” is selected, in order to extract only this type of objects from the map. The two maps in Figure 2 show the building footprints related to the satellite images shown in Figure 1.

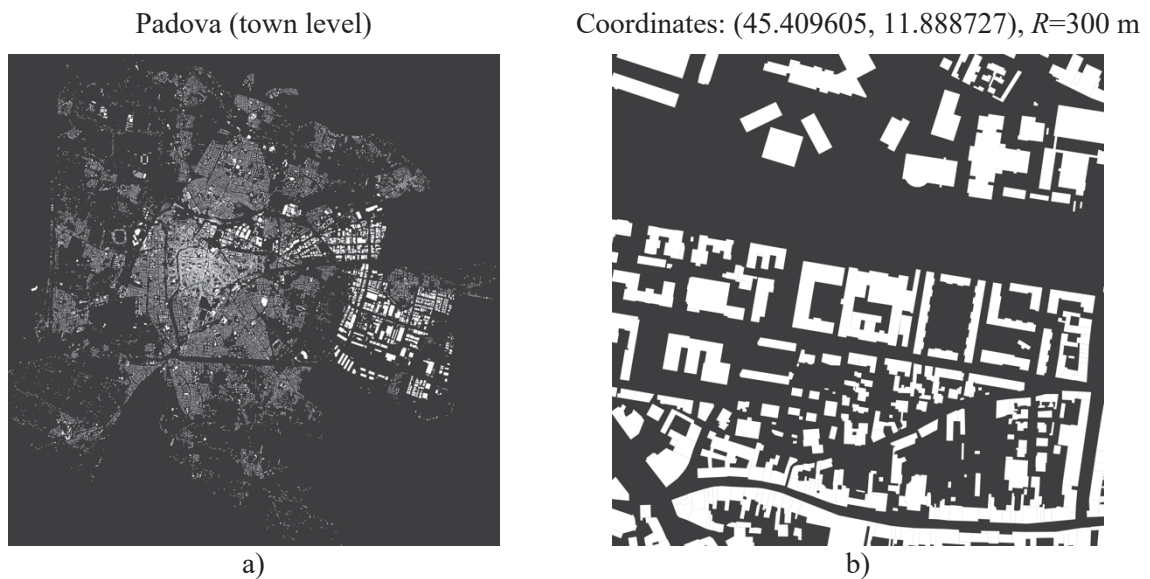

Figure 2: Building footprints for a) the town of Padova, b) an area centered in the point of coordinates (45.409605, 11.888727) with a radius of 300 meters

This section of the code not only retrieves the building footprints, but also retains their floor area, their centroid (latitude-longitude) and the labels of each building (such as “accommodation”, “commercial”, “religious”, etc). All the data obtained are stored in a DataFrame, where each row represents a building; they can be accessed and edited via GeoPandas, an open source project that helps manage geospatial data in Python. Figure 3 shows the building footprints from Figure 2b, with different colors according to their label.

Figure 3: Building footprints and their labels

In addition, the way in which data are stored makes it easy to filter them. As an example, only residential buildings and their outbuildings are shown in colors in Figure 4, while other building typologies are plotted in gray.

Figure 4: Building footprints and their labels, where only residential buildings and outbuildings are kept

As said before, for each building the centroid is known. Thanks to the Google Street View API, it is possible to automatically obtain the façade picture of a desired building, given its centroid coordinates. The user can select the size of the output picture, the pitch (vertical angle) and the heading (horizontal angle). In this work, the default size was chosen, i.e., 640x640 pixels. Also, no heading was specified: each time, a value is calculated that directs the camera towards the specified location, from the point at which the closest photograph was taken. For what concerns the pitch, an angle of 5° was selected, so that even taller buildings can fit in the

image taken (the default value would be  $0^\circ$ , which means flat horizontal). In Figure 5, some examples of street view images associated to the area under consideration are shown. The code could easily acquire the street view pictures for all the building footprints in the image, in a fairly short computation time.

Figure 5: Examples of street view images obtained from the coordinates of the building footprints

### 3 AUTOMATED ESTIMATION OF BUILDING HEIGHTS

The workflow described in §2 leads to a good estimate of building exposure in a specific area, in terms of number of buildings, building typology and total built-up area.

As said before, however, such information is not sufficient to predict the seismic vulnerability and risk level of a urban district, since more building parameters should be evaluated. In particular, previous works have shown that a good estimate of vulnerability can be obtained by knowing at least the number of stories, the material and the construction period of the buildings examined [5].

In this paper, the variable “number of stories” is examined. Specifically, an algorithm that automatically retrieves the number of floors of buildings from street view images was developed. Image processing and feature extraction techniques were implemented in this algorithm.

#### 3.1 Building detection with bounding boxes

The first step in this algorithm is the correct identification of buildings in the street view image. To perform this task, other works have used Convolutional Neural Networks (CNNs) that are able to detect and classify façade structures from street view pictures [9].

In this specific case, however, a complete detection of buildings is not necessary. In fact, to estimate the number of stories, only a single vertical strip of windows could be sufficient. For this reason, a script that selects the appropriate bounding box was developed. A bounding box is a rectangle that fully encloses an object in a digital image; in this case, the bounding box is set to include one or two vertical strips of windows (optionally including the door), going from the bottom of the building (e.g pavement line) to the rooftop (e.g skyline). In this way, the rest of the code will only have to deal with a smaller portion of the detected building, thus reducing the computation time and possible overlapping errors.

The method used to detect a bounding box relies on the Hough transform. The Hough transform is a feature extraction technique often used in digital image processing, whose main purpose is the identification of lines in the image [25].

Firstly, only the vertical Hough lines are taken into consideration, with a range of slopes between  $-15^\circ$  and  $+15^\circ$ , where a  $0^\circ$  represents a perfectly vertical line (green lines in Figure 6b). By doing so, vertical strips of windows can be easily defined.

Secondly, the ground and the sky must be detected. Also in this step, the Hough transform is utilized, keeping only the lines whose slope is between  $60^\circ$  and  $90^\circ$  (both positive or negative). These values were chosen to make it possible to detect the base and the rooftop of a building, even when the street view image is not perfectly frontal. For detecting the skyline (blue line in Figure 6b), only the top half of the street view image is considered, while for the bottom line of the building (red line in Figure 6b) only the bottom half is kept. The fact that the street view images are acquired with pitch angles of  $5^\circ$  helps to remove part of the pavement, which is an irrelevant element for creating the bounding box.

The code was written in MATLAB, and more information about the parametric representation of lines with the Hough transform can be found in the algorithms section of the mathworks page.

In Figure 6c, it can be seen that from a rather complex street view image (with more than one building, a car, a gate, trees), the algorithm is able to crop only the part of the picture that will be useful for the estimation of the number of stories.

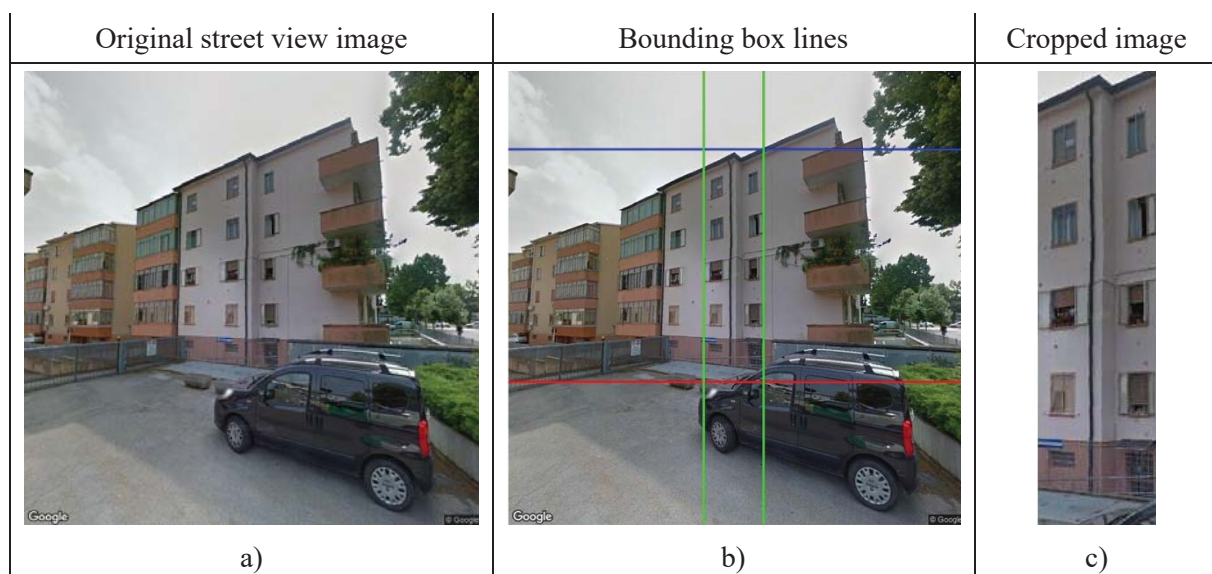

Figure 6: Example of a bounding box

### 3.2 Feature extraction for estimating the number of stories

Now that only a meaningful part of the street view image has been selected, the algorithm can proceed with the estimation of the number of stories. The key concept of this step is that the top and bottom of every door and window (or row of windows) must be detected, so that they can be associated with the presence of a floor.

To begin with, the raw Google Street View image has to be processed. Firstly, the original picture is turned into a grayscale image, and then an edge detection method is implemented. Edge detection is an image processing technique for finding the boundaries of objects within images, which works by detecting discontinuities in brightness. This technique is commonly used for image segmentation and data extraction. In this work, a Canny edge detection method

is implemented [26]. This method finds edges by looking for local maxima of the gradient of the grayscale image, which is calculated using the derivative of a Gaussian filter. The Canny method is one of the most suitable to detect true edges. The result is a binary (black and white) image, as shown in the example of Figure 7c for a bounding box image.

Secondly, morphological operations are applied to the binary image. These operations can process images based on shapes, so that each pixel in the image is adjusted based on the value of other pixels in its neighborhood. In particular, the following morphological operations are used: *skeleton*, which removes pixels on the boundaries of objects but does not allow objects to break apart; *thin*, which thins objects to lines; *spur*, which removes pixels starting from the end of any branch as well as the two ends of the main skeleton; and lastly *clean*, which removes isolated pixels. Essentially, all these operations allow a simplification of the binary image, where only the main lines are kept (as can be seen in Figure 7d).

The final step is the window (and consequently floor) detection. Once again, the Hough transform was used to detect horizontal lines, as described in §3.1. Out of all the lines that are found, the ones that are too close to each other (i.e., at a distance of less than 20 pixels) are grouped together, and only one of them is kept. This solution was adopted in order to avoid detecting the same line twice, since the border of a window may be associated with multiple Hough lines. In addition, the script eliminates intersecting lines, which are usually caused by obstacles in front of the actual window or door, such as the branches of a tree.

Figure 7 shows the general workflow that has just been explained. In Figure 7a, the original street view image is shown, as obtained from Google Street View. Figure 7b shows the bounding box that selects only the main door and one strip of windows. Figure 7c shows the result of applying the Canny Edge method to the bounding box image, while in Figure 7d morphological operations are applied to the binary image. Lastly, Figure 7e represents the feature extraction step, where the Hough transform technique is used to identify the lines delimiting doors and windows.

Looking at Figure 7e, the estimation of number of stories is immediate, since every couple of lines represents a different floor. Moreover, the code automatically computes this parameter, by taking into account the final number of lines, dividing it by two and rounding this value down.

Original street view image	Step 1: Bounding box	Step 2: Canny edge detector	Step 3: Morphological operations	Step 4: Hough lines (stories)
				
a)	b)	c)	d)	e)

Figure 7: Main steps of the algorithm to estimate the number of stories of a building from street view images

### 3.3 Particular case: bounding box for hidden buildings

The code described in §3.2 works with a good degree of accuracy when the building is completely visible, and the façade can be seen from a frontal or near-frontal perspective. However, many Google Street View images contain pictures of buildings that are partially hidden or covered by obstacles. In order to cope with this problem, some adjustments were made in the algorithm. Here, the case where a tree blocks part of the picture is commented.

In the example provided in Figure 8a, tree branches and leaves occupy almost the entire top half of the picture. When applying the Canny edge detector to this type of images, a lot of noise (in terms of blobs and irregular shapes) is generated in association with these objects, as can be seen in Figure 8b. This may affect the performance of the code, since the Hough transform method may mistake lines belonging to the branches for window lines.

Fortunately, the building that has to be detected (the one in the middle) is not concealed, and the base and rooftop are both visible behind the tree, as well as the door and the windows. For this reason, some specific morphological operations can be performed, so that the lines and dots belonging to the leaves are deleted, and the algorithm is able to operate only with lines associated to the actual building. In particular, the operation called *branchpoints* is used, which finds lines connected to the main objects of the image. Subsequently, the branchpoints are enlarged, in order to really separate the lines. Then, the branchpoints are erased from the original binary image to leave just the single, unbranched lines, as shown in Figure 8c. Lastly, the blobs that are formed by less than  $n$  pixels can be deleted (in this work, a value of 30 pixels was chosen), and the result is shown in Figure 8d. In this last image, it is clear how the noise due to the tree can be almost completely removed, maintaining only the main lines of the building under consideration. Figure 8e shows the bounding box related to the building, and it can be noticed how the algorithm can detect the façade without being influenced by the tree or other elements.

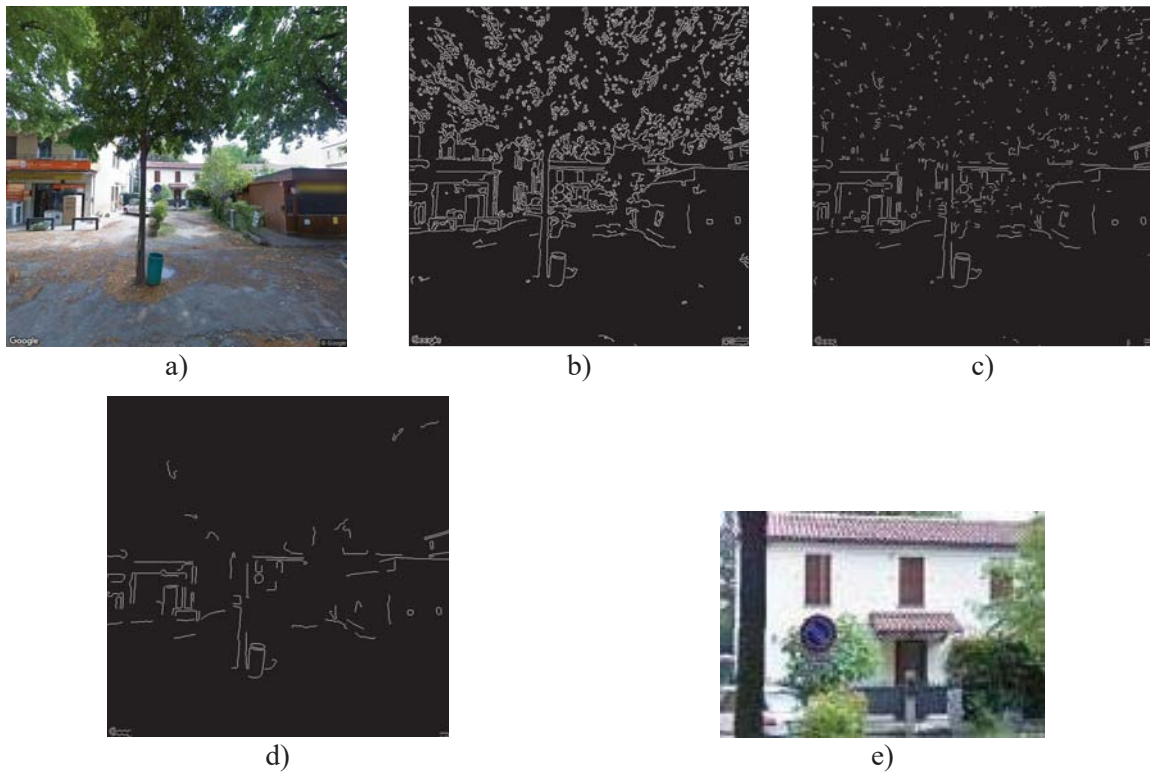

Figure 8: Example of bounding box for a street view image with an obstacle (tree)

## 4 CONCLUSIONS

- An algorithm that automatically retrieves satellite images from a pair of coordinates or a town name was discussed. The code also returns the building footprints that can be found in the image, together with their coordinates, areas, and labels. These data can be edited, and the resulting map can be filtered. The following part of the algorithm uses the coordinates of the buildings found in the area to acquire street view images.
- A second algorithm was presented, to estimate the number of stories of the buildings found from the previous code. The street view images obtained before are the input of this algorithm. Firstly, the code creates a bounding box that selects only the part of the building that is sufficient to estimate its number of stories. Secondly, the number of stories is evaluated through image processing and feature extraction techniques, particularly the Canny edge detection method, morphological operations and the Hough transform. In addition, some particular cases where the building is hidden by obstacles were treated.
- The work presented in this paper is in phase of validation. The code works best for buildings that can be seen from a frontal perspective, although some expedients were adopted for images that do not have the same characteristics. However, a more systematic validation should be carried out, involving different areas, different territorial scales, and different building typologies.
- This work fits into the wider context of automated seismic risk assessment. In order to carry out risk analysis, the estimation of the height parameter is not sufficient to achieve an acceptable level of accuracy. Other variables will have to be evaluated, first of all construction period and material. Once all these parameters are known, it will be possible to estimate seismic vulnerability more accurately and automatically at a territorial scale. Therefore, this algorithm could represent a useful tool for authorities in the field of seismic risk management, and it could make on-site surveys unnecessary, with a remarkable reduction in time and costs.

### Abstract

*Based on past earthquake events, bridges are the most critical and usually the most vulnerable components of road and rail transport systems, while bridge damage is related to substantial direct and indirect losses. In view of this, the need for direct and reliable assessment of bridge vulnerability has emerged, and several methodologies have been developed using probabilistic analysis for the derivation of fragility curves. A new framework for the derivation of bridge-specific fragility curves is proposed herein, introducing machine learning techniques for a reliable estimation of limit state thresholds of the most critical component of the bridge system (which in standard -ductility based- design is the piers), in terms of a widely used engineering demand parameter, i.e. displacement of control point. A set of parameters affecting the seismic capacity and the failure modes of bridge piers is selected, including geometry, material properties, and reinforcement ratios for cylindrical piers. Training and test sets are generated from multiple inelastic pushover analyses of the pier component, and Artificial Neural Networks (ANN) analysis is performed to derive closed-form relationships for the estimation of limit state thresholds. The latter are compared with closed-form relationships available in the literature, highlighting the effect of machine learning techniques on the reliable estimation of bridge fragility curves for all damage states.*

**Keywords:** Bridge fragility curves, Limit state thresholds, Machine learning techniques, ANN

## 1 INTRODUCTION

There is an increasing trend for assessment and retrofit prioritization of existing infrastructure in earthquake-prone areas, as well as investment planning, to be based on reliability analysis results. In this context, numerous methodologies have been proposed during the last 30 years for the derivation of bridge fragility curves, with increasing accuracy and efficiency over the years, introducing the use of advanced computational methods and probabilistic framework for the estimation of the probability of damage for different levels of earthquake intensity and limit states. The majority of the methodologies proposed are analytical, differing mainly in the quantitative definition of limit states (LS), i.e., the threshold values of LS considered, the type of analysis, the uncertainty treatment, and the probabilistic model used for the fragility analysis (probabilistic seismic demand model, response surface models, meta-models) [1, 2]. Both generic and bridge-specific fragility curves have been proposed, accounting for the various uncertainties in seismic capacity and demand estimation of critical components, and a few of them for the effect of case-specific properties on the results.

Very recently [3], the potential exploitation of Artificial Intelligence algorithms and Machine Learning (ML) techniques in earthquake engineering, (i.e., seismic hazard analysis, system identification and damage detection, seismic fragility assessment, and structural control for earthquake mitigation) has been explored; it is still at a rather early stage, but a promising development. ML algorithms can be classified into supervised learning and unsupervised learning type. Supervised learning uses prior knowledge of the labeled data set to learn a function that best approximates the relationship between input and labeled output in the data. In contrast, unsupervised learning aims to infer the natural structure from a set of data points that have no target labels [3].

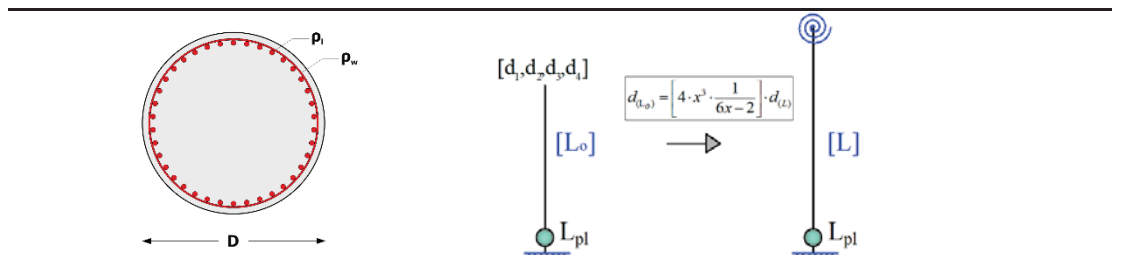

Several machine learning tools (i.e., classification-based tools like random forest, neural networks, etc.) have been proposed and applied to assess bridges and derive fragility curves. The efficiency of ML techniques for the derivation of fragility curves for different bridge classes and the identification of the effect of parameter uncertainties on the results have been studied for different bridge types and structural systems [4], [5]. Furthermore, the capabilities of machine learning techniques have been used to check the validity of assumptions during fragility analysis of bridges (e.g., the assumption of lognormal distribution of the demand model, etc.) [6]. Rapid damage assessment of bridges has been proposed based on analysis of selected bridge classes using the prediction model established via the training set and evaluating the performance of the model using the test set, as proposed in [5]. Based on the above, it is clear that the use of ML algorithms in the frame of fragility analysis of bridges is a new, promising approach that could eventually drastically reduce the computational effort and increase the accuracy and the efficiency of fragility analysis. However, since fragility analysis includes multiple steps and calculations (i.e., capacity, demand, uncertainty, etc.), the use of ML techniques at several stages should be properly addressed.

In view of the above, a methodology for the derivation of bridge-specific fragility curves that has recently been proposed by the authors [7], and is applicable to bridge stocks will serve as the starting point for setting up a ML procedure. The aim of this paper is to develop and apply ML algorithms (Artificial Neural Networks (ANN)) for a more reliable estimation of bridge pier capacity and limit state thresholds for all limit states (minor damage to collapse) considered in fragility analysis. A set of parameters affecting the seismic capacity and the failure modes of cylindrical bridge piers is initially selected, including geometry, material properties, axial load and reinforcement ratios. The range of parameters is selected with a view to representing realistic cases and resulting in training and tests of sufficient size. Analysis at local level (pier section) and global level (inelastic pushover analysis of bridge compo-

nents) is performed and the results in terms of a widely used engineering demand parameter (EDP: displacement of control point/drift) are recorded. Test and training sets are generated from the results of numerous inelastic pushover analyses, and Artificial Neural Networks (ANN) analysis is performed, resulting in closed-form relationships for the estimation of limit state thresholds. The latter are compared with closed-form relationships derived through ‘standard’ regression analysis, in the frame of the methodology described in [7], to study the effect of ML techniques on the accuracy of the limit state threshold definition and, eventually, its potential for estimating bridge fragility curves for all limit states.

## 2 COMPONENT-SPECIFIC LIMIT STATE THRESHOLDS AND PROPOSED CLOSED-FORM RELATIONSHIPS

Utilising the methodology described in [7], component-specific limit state thresholds are estimated for bridge piers in terms of displacement at the component control point (pier top). Closed-form relationships relating  $d/h$  to the parameters affecting the seismic performance and ductility of bridge piers, namely geometry, material properties, longitudinal and transverse reinforcement ratios, and axial load, are derived for all limit states (minor damage to collapse). Limit state thresholds are initially defined qualitatively and subsequently quantitatively at local (section) and global (component) level.

<i>Inelastic Pushover Analyses Performed</i>							<b>36,000</b>

Table 1: Cylindrical pier section and component parameters considered.

A broad range of different pier section properties described in Table 1 are considered, and section analysis is performed using an in-house developed software that provides bilinearised moment-curvature ( $M-\phi$ ) curves [8]. Damage is initially quantified in terms of material strain limit values, namely  $\varepsilon_c$  and  $\varepsilon_s$  corresponding to experimentally observed crack widths, and moment corresponding to loss of bearing capacity for limit state 4 (post-peak  $M=0.9 \cdot M_{\max}$ ). More details regarding local limit state definition are available in [7]. Based on cross section analysis, moment-curvature curves are derived (and bilinearised) and curvature values corresponding to the aforementioned material strains are defined. Hence, damage is initially quan-

tified in curvature terms (*local* EDPs  $\phi_1, \phi_2, \phi_3, \phi_4$ ), and  $M-\phi$  curves, as well as effective stiffnesses  $EI_{\text{eff}}$  ( $M_y/\phi_y$ , needed for pushover analysis) are defined. Section analysis results for all possible parameter combinations (7,200 section analyses), are obtained; a sufficiently broad range of heights is considered, and parametric setup of an inelastic cantilever model (Fig.1) is performed in order to perform inelastic pushover component analysis (36,000 pushover analyses, see Table 1). Plastic hinge formation is considered at the pier base (lumped plasticity model), while the bilinear  $M-\phi$  curve is used as input. Inelastic pushover analysis is performed for all sections considered paired with all different pier heights, and the global engineering demand parameter values ( $d_1, d_2, d_3, d_4$ ) are recorded at the analysis step that the relevant local values ( $\phi_1, \phi_2, \phi_3, \phi_4$ ) are exceeded. Check for shear failure, calculating the displacement ( $d_v$ ) when shear strength  $V_u$  is exceeded is performed, considering reduced concrete contribution in the inelastic range [1];  $d_v$  is compared to the displacement at flexural failure ( $d_{fl}$ ) and the minimum value is considered as threshold value for the limit state (Fig.1).

Table 2: Closed-form relationships based on regression of analysis results.

The pushover analysis results ( $d_1/h \sim d_4/h$ ) of the extensive parametric study are obtained, and regression analysis (considering the parameters in logarithmic form and performing nonlinear

fit) is carried out to derive closed-form relationships for cylindrical piers. The proposed closed-form relationships for the estimation of limit state thresholds ( $d_1 \sim d_4$ ) and, eventually, of seismic capacity, are provided in Table 2.

### 3 METHODOLOGY FOR THE DERIVATION OF LIMIT STATE THRESHOLDS USING ML TECHNIQUES (ANN)

An alternative method for the estimation of pier LS threshold values in the context of bridge-specific fragility analysis is introduced herein, entailing the use of ML techniques, i.e., Artificial Neural Networks (ANNs), trained to predict  $d_1 \sim d_4$  values calculated from inelastic pushover component analysis. The use of ANNs in engineering problems is common; however issues like high bias (i.e., not enough complexity to describe the input data) and high variance (i.e., overfitting), should be avoided, as described in [9], where additional information regarding ANNs is provided.

The first part of the methodology is the same as the one proposed in [7] and described in §2, i.e. a range of parameters is selected and paired in order to perform section and component analyses and estimate limit state thresholds in displacement terms. The range of parameters, selected in order to represent realistic cases and result in training and tests of sufficient size, is presented in Table 3.

Parameters	Training & Test Sets		Number of Param.
	Range	Step	
D (m)	1.5 - 2.3	0.1	[9]
$\rho_l$	0.005 - 0.03	0.0025	[11]
$\rho_w$	0.0025 - 0.015	0.0025	[6]
$\nu$	0.1 - 0.3	0.02	[11]
$f_c$ (MPa)	16 , 20 , 25 , 30		[4]
$f_y$ (MPa)	220 , 400 , 500		[3]
H (m)	2.5 , 5 , 10 , 15		[4]
	Analyses Performed		<b>313,632</b>

Figure 2: Function code (python) for  $d_1$  closed-form relationship

A total of 313,632 pushover analyses were performed and used for training and testing of ANNs (half of the total set size used for training and the other half for testing). Different ANN sizes were examined (i.e. 5-5-5-1, 5-5-5-5, 5-10-10-1, 5-15-15-1) to select the most efficient in terms of recorded MAE (mean absolute error) and MPE/MNE (maximum positive and negative errors). The 5-10-10-1 (two inner layers of 10 nodes each) was found the most appropriate ANN size, since the recorded errors did not differ significantly from the ones of 5-15-15-1 size and were apparently lower than those recorded when 5-5-5-5 was applied. The training procedure produced four closed-form relationships (functions) for the considered pier type (cylindrical pier) and all limit states. All analyses presented herein have been carried out using Python / TensorFlow 2.5 and a typical format of the relationship proposed for  $d_1$  is provided in Figure 2. Testing of the relationships for  $d_1 \sim d_4$  was performed using the test set described above, estimating the errors to establish the accuracy of the proposed relationships and their efficiency towards limit state thresholds estimation.

#### 4 COMPARISON

To evaluate and compare the closed-form relationships proposed herein based on the training/testing of ANNs, with those proposed in [7], derived from regression analysis, the diagrams of drift  $(d/h)_{\text{analysis}}$  values and the error resulting from the proposed relationships  $((d/h)_{\text{predicted}} - (d/h)_{\text{analysis}})$  are calculated for both cases, providing the relevant plots and the fit indicators, i.e. the MAE, MPE, MNE and the RMSE (Root Mean Squared Error) and  $R^2$  (Root Mean Squared Error).

Figure 3: Comparison of  $d_1$  prediction error of the closed-form relationships proposed in [7] and application of ML techniques (ANN)

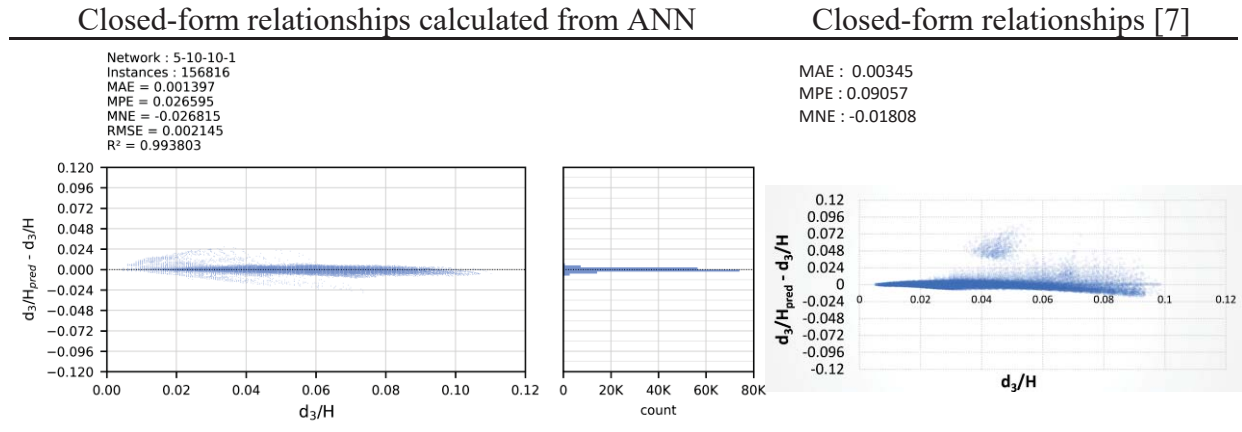

Figure 4: Comparison of  $d_2$  prediction error of the closed-form relationships proposed in [7] and application of ML techniques (ANN)Figure 5: Comparison of  $d_3$  prediction error of the closed-form relationships proposed in [7] and application of ML techniques (ANN)Figure 6: Comparison of  $d_4$  prediction error of the closed-form relationships proposed in [7] and application of ML techniques (ANN)

From Figures 3 to 6 it is clear that the values of MAE, MPE, MNE are lower in the case of the relationships proposed herein based on ANN training, compared to the ones proposed in [7]. The new relationships show a better fit of data, on the basis of the low RMSE and high R<sup>2</sup> values (0.987~0.996 instead of 0.75~0.80 of the new relationships), i.e. better prediction of the LS thresholds for all LS. The reduction of the prediction to analysis mean absolute error (MAE) ranges from 2 to 2.85 times, while it is obvious that the error reduction is larger for the higher limit states ( $d_3$  &  $d_4$ ), wherein the data fit based on regression analysis proposed in [7] was found inadequate.

## 5 CONCLUSIONS

The effectiveness of ML algorithms (ANN) for the quantitative estimation of limit state thresholds and the derivation of closed-form relationships (functions) used for seismic capacity estimation in the frame of a bridge-specific methodology proposed by the authors [7] was investigated herein. The closed-form relationships proposed within the methodology described in [7] which are based on regression of parametric inelastic analysis results of bridge piers are compared with those estimated based on extensive parametric analysis results used

for training and testing of ANNs. The parameters considered for both cases are the same (geometry, material properties, axial load and reinforcement ratios), however the approach proposed herein is differentiated regarding the number of parametric analysis performed for the development of training and test sets and the application of ANNs, instead of typical regression analysis. The most important findings related to the effectiveness of ML techniques and the increased accuracy achieved during the quantitative limit state threshold definition and, eventually, the estimation of bridge fragility curves for all damage states, are:

- The relationships derived herein based on ANN training, have lower error (MAE, MPE, MNE) and high  $R^2$  values, indicating better fit of data; i.e. better prediction of the LS thresholds for all LS, compared to those proposed in [7] derived from regression analysis.
- The reduction of the prediction to analysis mean absolute error (MAE) ranges from 50% to 65% when ANNs are used for closed-form relationship estimation.
- The error reduction is larger for the higher limit states ( $d_3$  &  $d_4$ ), where the data fit based on regression analysis proposed in [7] was found inadequate. The latter is due to the increased sample size used and the training/testing of ANNs.
- The relationships proposed herein for the estimation of limit state thresholds for cylindrical piers ( $d_1 \sim d_4$ ) indicate in general better fit to analysis data, hence providing more accurate and reliable prediction of component capacity and, eventually, seismic fragility.

## ACKNOWLEDGEMENTS

### Abstract

*In this work, quantitative evidence on whether the aesthetic value of architectural design is associated with its structural response is investigated. The procedure for this study was based on 170 parametric projects, as well as their structural analysis results. The aesthetic value of an architectural project is an ambiguous concept, as it is based on each individual's perception of beauty. This is highlighted in the corresponding literature on parametric design, form-finding, and aesthetics, as well as in an extensive bibliometric analysis of several hundreds of research papers with respect to aesthetics and structures. Henceforth, a questionnaire was developed and given for vote to 23 persons from a variety of disciplines such as architects, engineers, as well as people with profession irrelevant to structures and/or aesthetics. The mean value of the votes of the questionnaire was considered as the dependent variable of the mathematical model, while the structural response parameters, internal forces and nodal displacements, were set as the Independent variables of the model. The obtained data were analyzed with regression analysis, utilizing linear and machine learning models, revealing a significant link between structural response and aesthetics.*

**Keywords:** Building Aesthetics, Structural Behaviour, Structural Analysis, Machine Learning, Regression Analysis.

## 1 INTRODUCTION

Architectural design is highly dependent on structural behaviour and a variety of studies exist in the corresponding literature. Monedero [1] has performed an analysis of the existing literature on parametric design, stating that in the last few years there has been an evolution in technology, while architects have started using it to their advantage. In particular, parametric design is a process of mathematical and programming algorithms, which creates multiple components and operations, assisting the designer to create any complex artifact from simple lines and curves to a composite project which is usually difficult to understand, but it's beautiful aesthetically. By utilizing structural plugins such as Katamba 3D [2]–[6], the creator can investigate the structural analysis results during the architectural design, and change the project so as the structural configuration will be adequate. Shells have been a frequent object of research [7] as it is often seen in nature. Santiago Huerta [8], explains that Gaudi had been using physical models and graphic methods to support his designs. Accordingly, huge columns support the domes of the Sagrada Familia which bring to mind trees. Similarly, by utilizing computer algorithms, Miloš Dimčić [9] demonstrates that by using the same surface and the same number of points, which can be structural objects, you can create a number of different batches that have better structural behaviour than other ordinary objects. Furthermore, at the Post Rotterdam, which has been refurbished [10], the redesign of the building had been done with the aid of Grasshopper3d [3], a software capable for parametric design, in combination with other software in order to find the optimum structural response based on form-finding. The author concludes that these types of tools in design help a lot in finding an ideal figure and furthermore performs excellently in regards to the structural part of the design by making calculations in a short period of time.

In a review paper [11], John S. Gero refers to the fact that after the 19th century, architecture is not considered only as art but also as a science-based on its evolution at its current stage. As a conclusion, he states that architecture combines science that doesn't only create forms and objects but also adjusts them with reference to the human factor in combination with its structural analysis. Natural forms are not drawn or created based on aesthetics but on their structural behaviour in combination with different types of materials [12]. Famous architects like Antonio Gaudi, and to some extent Luigi Nevri and Frei Otto have studied these natural forms in order for them to conclude and create a more natural and organic architecture. The conclusion of this study is that if an architect studies organic designs, he discovers a new world, says the author. To achieve this, one needs a lot of different trials, with different methods, considering environmental issues, materials, engineering and often he refers to pure luck. Michela Turrin [13], refers to the advantages that arise from the parametric design and how easy one can find different forms with the same rationale. She continues by explaining that this is key in the architectural form. Paolo Basso [14] explains that all organic geometric forms that exist are arranged and can be configured based on the NURBS curves, concluding that in the fields of both architecture and engineering new methods need to be found in regards to research, analysis and resolution. The approach of parametric design or other software that use NURBS curves gives the user full control over the smoothness of the object that is being created.

In a statement on Frei Otto [15], Boho Rasch mentions that Frei Otto is fascinated by organic, physical forms (the same happens when we minimize the inclination forces), and lightweight construction. He also states that the architect uses computer-aided means and the vast potential they have in order to specify the shape and behaviour of such organic forms. He concludes that Otto believes in the organic, lightweight form as he believes that it improves the human health and mood, but also nature itself. Renaud Aleis Pierre Emile [16] refers to

the current tools of design and analysis, as being highly powerful and that they can allow someone to produce and analyze any structural form. However, most of them are not allowed to use such means in the pure design stage of a project. The parametric design allows for a rapid study of complex geometric shapes and can be combined with an algorithmic analysis and optimization to design with performance as a parameter as well as objective. In his conclusions, he states that his work reflects that parametric design can be extended by using ground breaking computer-based ideas in the research for design with an epicenter to perform in creative ways.

Neri Oxman [17], mentions that the recent development of computer-based geometry and the expansion of the CAD software packages that support geometrical model design, combined with the research on design, lead to the evolution of analysis tools. Such tools have now been expanded in order to include complex computerized methods for non-Euclidean geometries, such as the B-spline curves and the NURBS surface. Hence, there will be a new model that studies the form and the implementation of design at the same time. If such an emersion is possible, then this knowledge that computerized geometry offers will be one of the most important forms of disciplined knowledge in computerized design software in architecture. Allen Carlson [18], mentions that aesthetics and nature are directly linked and that the relationship between science and nature is controversial. He also supports the environment and the nature we live in has led us to each one of our own aesthetics. The need of nature is to create something functional and at the same time light [19]; which is a result of constant optimization, that has been going on for millions of years, and which will continue to be as long as this world exists. Accordingly, the concept of form-finding is a process of optimizing the static equilibrium of the structure, finding the corresponding structural form, and architectural synthesis at the same time. The theory of evolution of the species in nature has inspired computer scientists, to develop the so-called evolutionary optimization algorithms [20], [21]. The purpose of this work was to investigate whether the structural behaviour of an architectural artifact is linked with the beauty of the design. It was attained, by utilizing 170 parametric structures, and their structural analysis results, via machine learning techniques.

## 2 BIBLIOMETRIC LITERATURE REVIEW

In order to investigate the literature related to architecture, computational design and structural analysis, the following bibliometric techniques were implemented. Initially, the Google Books database [22], based on 25 million books was searched using Architectural design, parametric design, computational design and form-finding. In Figure 1, it is depicted that in the last few years, and in particular since 1960, more people have begun to look for and learn about parametric design and have also begun to deal with computational design and form-finding as well. Additionally, from Figure 1, it is derived there is a proportion in the world looking for architecture after parametric design and then for form-finding. Interestingly, these are the steps that an architect can follow to design an organic form.

Growth rates of scientific knowledge correspond to a doubling every 9 years [22]. Hence, a vast amount of research papers were investigated with respect to their keywords associations, utilizing a procedure developed in [23], [24]. Figure 2, is the bibliometric map for the keywords of the 1414 documents, obtained from a search in Scopus database [25], comprising the term aesthetics. The frequency of its keyword is indicated with a number before the text, while the size of the corresponding circle is proportional to this frequency. Furthermore, the distances between the circles indicate the number of co-occurrences of these keywords in the papers' database. Utilizing this clustering technique, two major clusters are constructed, one with aesthetics in the center, near with the perception, architecture design and innovation keywords.

Figure 1: Google Books results of search terms

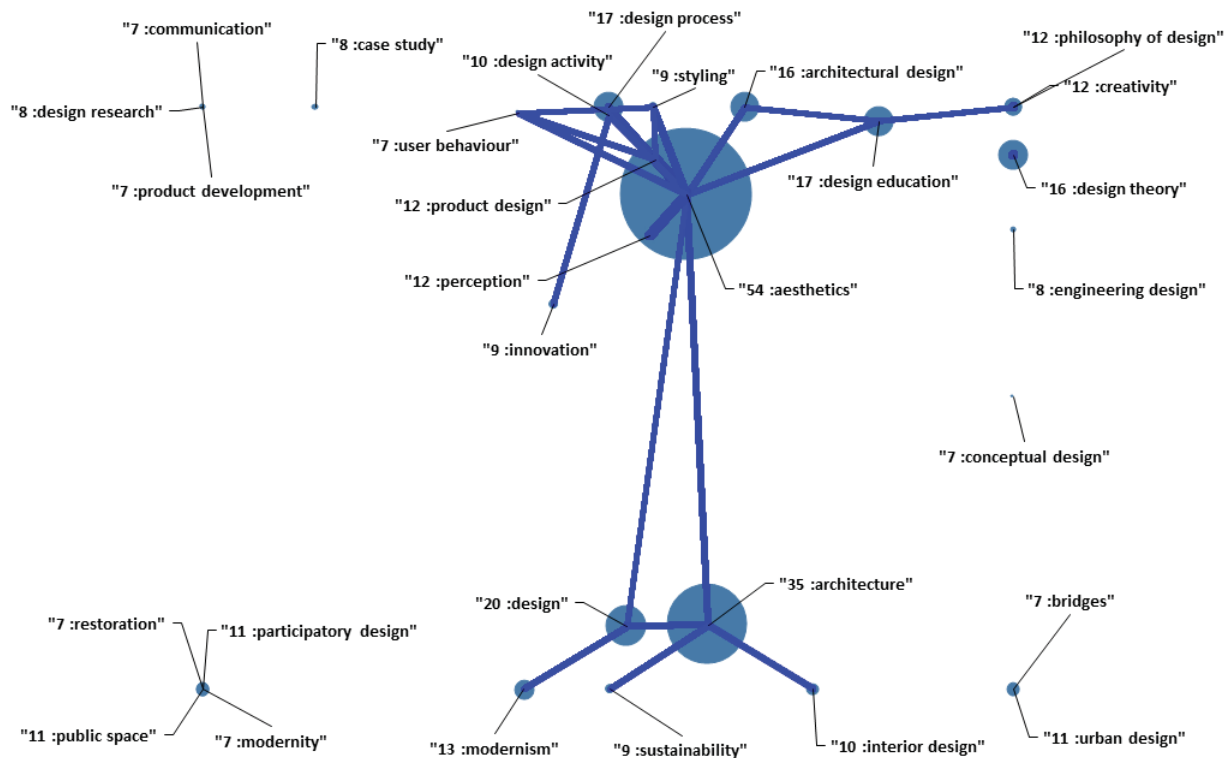

Figure 2: Scopus search for aesthetics

Accordingly, Figure 3, was created, by narrowing the search with the specific keywords of Table 1, as well as limiting the results with the generic keyword stuctur\*. Accordingly, tow clusters are developed, one at the bottom left side relative to the engineering literature with keywords structural engineering, engineering design, structural design- and another at the top right region of the map with keywords such as aesthetics, design process, perception etc.

### 3 STUDIED DATABASE

Seventeen projects have been used, of which all had ten different, parametric variations, by changing the slider components in the software [2], [3], and have been created mainly by the third-year students of the school of architecture at Neapolis University Pafos, in their modules, Computational Design and Advanced Structural Systems. From these ten alterations, we get sixteen structural analysis results, regarding the maximum and minimum displacements, nodal rotations, internal axial forces and bending moments. All these results are included in Appendix II, while indicative results are demonstrated in Table 2. These sixteen output values from each variation of the projects, in combination with a questionnaire which was completed by architects, engineers and other people, not related to this profession, will be analyzed statistically in order to investigate the hypothesis that structural response is correlated with the aesthetic value of each project. The aesthetic value was considered as the mean value (for each project) of the participants to this research. The questionnaire was filled by 23 people and the mean value of the responses was used as the dependent variable, representing an unbiased indicator for aesthetic value.

Table 2: Structural analysis results for structure 001-010

The numerical procedure was started by creating ten versions of each project by using the software Rhino [4], and its plugin Grasshopper3d [3] and then save ten renders from a different viewing point of each alteration. For the static solution of these projects the plugin Karamba3d [2], [5] was used, in which we came up with the maximum and minimum internal forces and also the maximum and minimum displacements. Furthermore, a questioner on Google docs (Appendix I), was created with all the images, which are included in Appendix III, in order for people to vote. From this feedback, an excel file was created so as to be analyzed with regression analysis. Furthermore, the top five projects that were voted, are demonstrated in Figure 7. Finally, two examples of the code that was used in Grasshopper3d, and one example code from Karamba3d are depicted in Appendix III.

In Figure 7 - A, which is a curved hanging bridge, the concept is to rotate around from its vertical axis to pass the ships under the bridge. Figure 7 - B, is a hanging bridge in a straight line similar to the previous one. In Figure 7 - C, we still demonstrate a hanging bridge of similar structural rationale, in the simplest form. In Figure 7 - D, we show a parametric shell with polygonal openings on the roof. Finally, in Figure 7 - E a large-scale enclosure is demonstrated. Accordingly, in, Figure10, the corresponding code in the Grasshopper3d [3] program and the congruent code is for the project of Figure 7-B. Then the code for the project of Figure 7-A is demonstrated in Figure 11 with an optimization tool to the right in order to find a place where the bridge has the minimum bending moments. Finally, for the same project, we see the

Karamba3d [2] code and the various values we output for moments and displacements (see Figure 12 in Appendix II).

## 4 HEADINGS

In order to perform the regression analysis, the results of each project were normalized to have zero mean and unit standard deviation, so as to utilize the same range for the Karamba3d results for its project and the statistical analysis to be more representative. The projects with irrational values of internal forces were excluded from the database via anomaly detection software [26], as they probably had errors in the connectivity of the model. We used three Machine Learning simulations, in order to construct prediction models, and in particular, Linear Regression [27], Random Forests [28], [29], and Gradient Boosting [30], [31], as developed in Julia [32] programming language. In Table 3, the accuracy metrics indicate a strong link among the structural analysis results, with the aesthetic value, as computed by the questionnaires. Afterwards, sensitivity analysis [33], [34] was conducted in order to investigate the influence of each independent variable to the dependent, by keeping all other variables constant at their Median value. In Figure 8, the corresponding results for Aesthetic value vs Bending Moments over Axial Forces are depicted, exhibiting a decreasing pattern. This is in accordance with the rationale of Antonio Gaudi [7] and the minimum bending moments of arches and domes.

Figure 5: Sensitivity analysis

Methods	Pears. Corr.	MAE	RMSE	MAPE	MAXPE	Alpha
Random Forests	0.8156	0.1460	0.1980	0.0466	0.2065	0.5704
Gradient Boosting	0.9732	0.0183	0.0771	0.0055	0.1761	0.9469
Linear Regression	0.3769	0.2449	0.3155	0.0800	0.3533	0.1154

## 5 CONCLUSIONS

This research was an attempt to contribute to the question of many architects and civil engineers on whether the structural response of a structure is useful to the stability of the building, or it has another utilization on the architectural synthesis as well. The literature regarding parametric design and form-finding, although indirectly refer to the aesthetics of the structure, lack any identification of a numerical link between the structural response and aesthetics of the structure. This was farther investigated and confirmed with bibliometric analysis of the literature regarding aesthetics and structural response, where the clusters of the aesthetic related keywords were separated from the engineering related keywords. An adequate amount of projects (170) were developed and studied in order to construct a database for such an investigation. The regression analysis confirmed numerically that there exists a link between structural response and aesthetics.

## 6 ACKNOWLEDGEMENTS

Special thanks to the students which participated in this study, by offering their studio projects:

Mais-Wakid Abbas, Theodoros Antoniou, Christina Georgiou, Rafaella Georgiou, Maria Giannaka, Panagiotis Kontopyrakis, Iuliia Logacheva, Maria-Pavlina Pavloudaki, Elina-Stergia Pieri, Demetris Socratous, Elenos Tsigkis, Maria-Evangelia Tzouveleki.

**Keywords:** High-Performance Computing, Deep Learning, Artificial Neural Network, Finite Elements, Nonlinear Analysis, Reinforced Concrete, Slender Beams.

**Abstract.** *Data-driven models employing artificial intelligence approaches have been increasingly utilized in structural analysis and design problems over the past two decades. The main applications involve the processing of datasets, which are gathered from experimentally derived records or obtained numerically, in order to develop closed-form formulae or numerical tools predicting quantities related to structural response and mechanical behaviour. Given that datasets are difficult to assemble due to the limited available information and the high cost entailed to enrich them, exhaustively processing the available data to produce the best possible prediction models is an essential task of particular interest. For specific applications, this exhaustive computing task involves large numbers of iterations performed to train detailed prediction models with large numbers of parameters. Despite the intense computational demands of such problems, limited research work exists on the scaling-up of the utilized algorithms on supercomputers. In this work, a distributed training and hyperparameter tuning algorithm is proposed for the modelling of the shear strength of slender beams without stirrups. The training dataset comprises results obtained from the detailed modelling and analysis of several beams with non-linear finite elements using the Reconan software. The results presented in this research work highlight the importance of optimally utilizing computational power for the solution of such problems. The developed computer code is available on GitHub.*

## 1 INTRODUCTION

Artificial intelligence techniques have emerged over the last decades as an effective and efficient tool to predict analysis outputs for computationally demanding engineering problems. Application areas requiring multiple analysis runs (design optimization, structural reliability, etc.) have largely benefited from various computational approaches eliminating the need for performing actual analyses by providing adequate estimations for the outputs of interest (e.g. [1, 2, 3, 4]).

The training process of an Artificial Intelligence model is itself a demanding task in terms of computational resources. Particularly, an Artificial Neural Network can comprise millions of parameters to train via iterative procedures, such as the stochastic gradient descent algorithm. These algorithms yield data structures that frequently cannot fit in the GPU (graphics processing unit) accelerators' RAM; hence parallelization is vital for the accomplishment of the training task, and obtaining accurate results. The optimization algorithms employed during the training process of a deep network can be parallelized by following either of two main routes. The first one is data parallelism [5, 6, 7], which foresees the splitting of the "batch of samples" (utilized in each iteration) into a number of smaller mini-batches, which are processed in parallel, depending on the number of available resources (GPUs). Alternatively, we may use model parallelism [8], by partitioning the deep learning model on distributed GPUs.

Despite the fast-pacing growth of deep learning, along with the vast need for computational resources, there are rather limited relevant engineering applications reported in the literature [9, 10, 11, 12, 13], none of which concerns reinforced concrete (RC) structures or slender beams. The purpose of this work is to investigate deep-learning algorithms for the prediction of the shear strength of RC beams. For the needs of this research work, detailed 3D finite element (FE) modelling of RC structures is adopted [14, 15, 16, 17, 18], in order to develop a large database of results on slender RC beams without stirrups. The numerically generated data set is then used to train models to predict the beams' shear strength. A new algorithm is designed and programmed, in order to be able to develop multiple input files (FE models) and efficiently analyze them through the use of the software Reconan FEA [19]. The newly developed algorithm (Reconan Multirun) and Reconan FEA were used to generate and analyse approximately 36,000 slender RC beams without stirrups; the obtained results were used for the training of the predictive models.

## 2 DATABASE ASSEMBLY

For each beam considered, 10 independent variables (input) and one dependent variable, which is the load corresponding to the ultimate strength (output), are varied. Particularly, the basic geometric variables are varied for each beam: the net span  $L$  (mm), the width  $b$  (mm), and the effective depth  $d$  (mm) of the beam. Apart from these variables that affect the FE meshing of the beams, strength and material related variables are also varied, and, particularly,  $f_c$  (uniaxial compressive strength of a cylindrical specimen in MPa),  $E_c$  (concrete Young modulus in MPa),  $f_t$  (concrete tensile strength ratio),  $\beta$  (remaining shear capacity strength factor),  $E_s$  (steel Young modulus in MPa),  $f_y$  (steel yielding stress in MPa), and  $\rho$  (tensile longitudinal reinforcement ratio).

Sampling for the 10 independent variables was performed uniformly as per Table 1, with the variables' coefficient of variation  $c_v = \frac{\sigma}{m}$  (standard deviation over mean) being kept within the range 0.2 to 0.5 [20]. Hence, for each group of beams, different values for geometric and strength variables were generated, and the overall database is finally constituted of 35,849

Table 1: Statistical metrics of independent variables.

	$L$	$d$	$b$	$f_c$	$E_c$	$f_t$	$\beta$	$E_s$	$f_y$	$\rho$
Minimum	1500.0	260.0	200.0	20.0	25000.0	0.020	0.020	$1.90 \times 10^5$	400.0	0.0010
Maximum	8700.0	1310.0	600.0	60.0	35000.0	0.100	0.050	$2.10 \times 10^5$	600.0	0.0200
$c_v$	0.416	0.406	0.228	0.305	0.097	0.404	0.252	0.029	0.115	0.627

observations in total. Out of the total database population, 85% was used as a training set and the remaining 15% was used for testing.

### 3 BASELINE AND MACHINE LEARNING MODELS

The predictive modelling of the database was implemented by utilizing four machine learning (ML) methods, and in particular Linear Regression (LR), Non Linear - higher order Regression (NLR) [21], Random Forests (RF) [22] as implemented in [23], and Gradient Boosting [24] (GB) as implemented in [25]. The performance of each ML method varies, and the Mean Absolute Percentage Error (MAPE) [26] was used as a meaningful metric for engineering applications. The MAPE in the test set for the four methods was 10.843 (RF), 12.178 (GB), 22.036 (NLR), and 32.211 (LR). Random forests exhibit the lowest MAPE for the test set, while LR the highest, which was expected as it is the simplest (linear) model used. Nonlinear regression (NLR) exhibits higher error than RF and GB, however, the NLR model is useful due to the closed-form formula that it generates. The distribution of ML models' residuals exhibited a shape close to the Gaussian, for all methods except the linear regression, which was skewed. This is due to its inability to capture the non-linear behaviour of the variables included in the model, highlighting the need for more complex ML models.

### 4 DISTRIBUTED DEEP LEARNING

PyTorch was used herein which is an “imperative style, high-performance deep learning library” [27], distinguished for scientific as well as industrial projects, due to a straightforward yet efficient implementation of an automatic differentiation algorithm [28]. For multi-GPU training, the Horovod [29] was implemented, a library that has been developed at Uber. Particularly, by using Horovod, one may take a single-GPU training script and efficiently scale it to run across many GPUs in parallel. With MPI commands [30], each process is initialized and is assigned its MPI rank in a straightforward manner, which is achieved with fewer code changes compared to other approaches. Ultimately, Horovod scripts can run on a single-GPU, multiple-GPUs, or even multiple hosts without any further code changes. Algorithms on various experiments were tested for the needs of this research work on the Cyclone Supercomputer<sup>1</sup>, utilizing PyTorch for computer vision as well as regression tasks<sup>2</sup>, highlighting the efficiency of data parallelism, as well as the scaling-up capabilities compared with standard ML platforms, such as Kaggle and Google Colab.

#### 4.1 Parallel Stochastic Gradient Descent

In Stochastic Gradient Descent, at each iteration, a random data-point  $i$  is selected, the Loss Function for this data-point is differentiated, and then the weights for the entire network are

<sup>1</sup><https://hpcf.cyi.ac.cy/>

<sup>2</sup><https://github.com/CaSToRC-CyI/artificial-intelligence-hpc>

updated. In mini-batch Stochastic Gradient Descent,  $i$  is the current “batch” of data, which is a subset of all dataset indices. The parallelization is performed at this point, by updating the weights for all batches in parallel. Hence, in Parallel Stochastic Gradient Descent, for each GPU (in parallel) a random data-point is selected, for which the gradient is computed and the weights are mixed. The average for the mixing of the weights can be implemented for this purpose, or other methods, such as ensembles, AdaSum, etc. Afterwards, the update of the weights for all GPUs takes place. In order to perform this operation in parallel, the utilization of MPI<sup>3</sup> framework is required, so as to gather the results among all GPUs, reduce, and broadcast them across all available GPUs again. This algorithmic procedure is described in Figure 1.

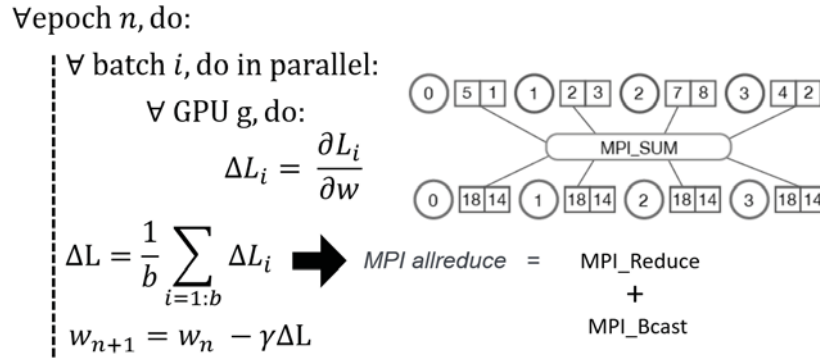

Figure 1: Parallel Stochastic Gradient Descent.

In general, it applies that, when using larger batch sizes the procedure becomes faster, and when adopting smaller batch sizes it becomes more accurate. In any case, the batch must fit into the relevant hardware memory, so the utilization of a larger number of nodes is required when a GPU cannot handle the batch size. Furthermore, in practice, the weights’ mix causes some accuracy losses. However, all these aspects regarding the computational behaviour of the Parallel Stochastic Gradient Descent procedure are not always absolutely valid, as the loss function is a highly non-linear function of the Artificial Neural Network’s (ANN’s) weights and depends on the dataset’s particular features, thus the computational procedure’s behaviour cannot be predicted. Therefore, the training of the network has to be performed by investigating a variety of architectures. In order to effectively treat this issue, hyperparameter tuning is adopted in the present work, and, ultimately, the training of a very large network on Cyclone supercomputer is attempted.

## 4.2 Hyperparameter tuning

In order to investigate the effect of the network’s hyperparameters, the Ray-Tune<sup>4</sup> module of PyTorch is implemented. Particularly, a number of ANNs are constructed by varying the batch size, the drop-out ratio, the number of Epochs and neurons, as well as the learning rate. Subsequently, the training of the networks is conducted. Accordingly, for each training example, the time for the training is recorded, while the final loss function and the ratio among the validation and train loss *Ratio V-T* are computed. The results obtained are presented in the Appendix. This

<sup>3</sup><https://mpitutorial.com/tutorials/mpi-reduce-and-allreduce/>

<sup>4</sup>[https://pytorch.org/tutorials/beginner/hyperparameter\\_tuning\\_tutorial.html](https://pytorch.org/tutorials/beginner/hyperparameter_tuning_tutorial.html)

is a time-consuming procedure, therefore, it was found useful to identify an optimal drop-out region of ratios [31]. As depicted in Figure 2, it can be concluded that, for lower drop-out values, the corresponding values of the loss function are also lower. However, as will be explained below, the drop-out could not be zero.

Figure 2: Ray-Tune results.

### 4.3 Combination of MPI & Horovod

During the training of an ANN, the loss function is automatically recorded, as loss is the core function that is differentiated to update the weights. In engineering applications, the Mean Squared Error (MSE) does not offer meaningful information, and the MAPE is being utilized as a more practical metric. Accordingly, as the best ANN's architecture is not known in advance, and given that multiple experiments must be performed, it is necessary to record the MAPE during training in real-time. However, as the data are split and reside at many GPUs, an operator should be implemented that gathers the individual predictions to obtain an aggregated metric for the dataset as a whole.

For this purpose, a mix of Horovod with MPI is proposed. In Figure 3, three code snippets are depicted describing the implementation of such an operation. The overall operation starts with the initialisation of vector *pred* in the code at the upper right part of Figure 3, which is used later as a container of all results. The code at the upper left part imports the MPI module from *mpi4py* and gets the rank of each GPU. Afterwards, as shown in the code at the bottom-left part of Figure 3, after each step of the optimizer, a barrier is set to wait for all GPUs to finish with their numerical processes. Then, the responses *y\_train\_pred* of each GPU are stored in vector *pred\_i* and, with the *comm.gather* command, all results are placed in *pred\_i*. Finally, an additional barrier is introduced to wait for all GPUs to finish and concatenate the results in vector *pred* only for rank 0. At this stage, vector *pred* holds the concatenated predictions and can be utilized to calculate the MAPE.

```
from mpi4py import MPI
comm = MPI.COMM_WORLD
rank = comm.Get_rank()
torch.manual_seed(0)
```

```
for e in tqdm(range(1, EPOCHS+1)):
    if rank == 0:
        t1=time()
        pred = np.empty(0)
        predV = np.empty(0)
    else:
        pred = None
        predV = None
```

```
optimizer.step()
comm.Barrier()
pred_i = copy(y_train_pred[:,0])
pred_i = comm.gather(pred_i, root=0)
comm.Barrier()
if rank == 0:
    for ii in range(len(pred_i)):
        pred = np.concatenate((pred, pred_i[ii].detach().cpu().numpy()), axis=0)
comm.Barrier()
```

Figure 3: Combination of MPI and Horovod.

#### 4.4 Parallel training

Figure 4 demonstrates the learning curves for the model without using a drop-out and with a 10% drop-out. In the case of no drop-out (Figure 4, left), even though there is in general a decreasing tendency in MAPE with the number of epochs, a number of significant peaks are evident. This can be interpreted as an effect of the averaging of the weights in parallel, which is a source of error. However, with the utilisation of a 10% drop-out (Figure 4, right), smoother learning curves are achieved and the aforementioned phenomenon seems to be not activated. Furthermore, it should be stressed that the validation curve for 10% drop-out is lower than the training curve, which is very important for the generalisation of the results.

Figure 4: Drop-out effect on the loss function during training in parallel. The model with drop-out exhibits a validation loss history with lower values than the corresponding train curve.

It is noteworthy to state that a variety of experiments was performed to attain an optimal drop-out ratio. Figure 5 presents results for a drop-out equal to 0.01. As can be seen at the right part of Figure 5, when the validation curve is higher than the training curve, it practically stabilizes around a constant value. This is helpful during training, as over-training of the network will not cause over-fitting of the derived predictive model.

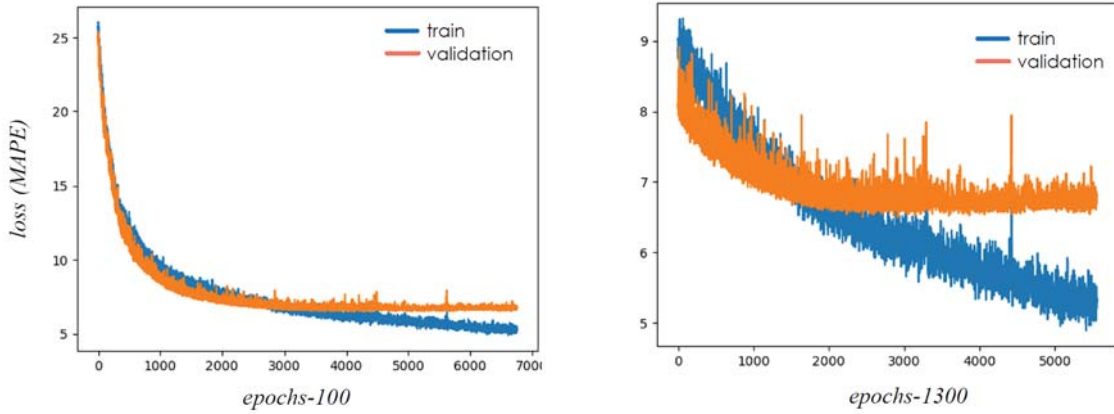

Figure 5: Results for low drop-out=0.01.

## 5 CONCLUSIONS

The numerical experiments performed in the present work comprised networks with large numbers of neurons, and thus, weights. For example, a network with 1000 neurons per layer and 10 layers corresponds to approximately 10 million weights to be optimised. As the most suitable network architecture is not known a-priori, several experiments need to be performed towards establishing the minimum possible error. Hence, computational power is vital for the best possible accuracy of the predictions.

It was also found that using PyTorch and Horovod as a functional solution for running deep-learning models on Cyclone Supercomputer is a very efficient approach. Furthermore, according to the parametric investigation performed in this research work, deep learning exhibited high accuracy in comparison to other ML methods. The best loss attained (MAPE) was 5.94%, while with Random Forests the corresponding loss was 10.7%, with Gradient Boosting 12.7%, Non-Linear Regression 24.0%, while Linear Regression had the worst numerical response with 32.3% loss.

The dataset under study comprised values with an increment of 10 kN and an average of 98.22 kN, thus an error  $\frac{10/2}{98.22} = 5.091$  inevitably occurs on average. Henceforth, any improvement of the 5.94% loss attained would be trivial. This highlights the power of deep learning on one hand, however, the computational demand for training as well as optimising the architecture of such networks is very expensive. Distributed training made these operations possible herein, achieving both efficient and accurate results.

## ACKNOWLEDGEMENTS

This work used resources from Cyclone Supercomputer<sup>5</sup> and was funded by the EuroCC project GA 951732. The use of computer resources under project Ispre519s1 of The Cyprus Institute is also acknowledged.

### Abstract

*The study of multi-degree of freedom (MDOF) systems is essential to evaluate and understand the seismic response of buildings. Through a MDOF idealization, the dynamic properties of the building such as its natural frequencies and modal shapes can be approximated. These properties are then used to determine the final design of the structural system of the building. A shear building MDOF system consists of an idealized model of the building in which the masses are concentrated at the floor levels and each floor is connected to other adjacent floors with elements that provide stiffness and only allow horizontal displacements. The dynamic properties of the idealized system are obtained by numerically solving a generalized eigenvalue problem which is a computationally expensive operation. In this paper, we propose a methodology to replace the required solution of the generalized eigenvalue problem with a Machine Learning NN-based approach. Two shear building models with 3 and 5 stories are considered, where the mass and the stiffness are held constant for every story. For every model, a database with the solution of several idealized models with varying mass and stiffness is created using a small number of samples ( $m$ ,  $k$  pairs). Finally, an Artificial Neural Network is trained with the database to predict the eigenperiods of other similar models avoiding the computation of the eigenvalue problem. The results show a high level of accuracy in the predictions and a significant reduction of the computational time compared to the hard-computing mathematical approach. Furthermore, the approach demonstrated in this study can be easily expanded to be applied to more complex dynamic systems for future research.*

---

## 1 INTRODUCTION

The field of structural dynamics covers the behavior of structures subjected to dynamic loading. Such loads include wind, waves, traffic, earthquake, blasts and others. In practice, the dynamic response of buildings is obtained by applying a series of assumptions and simplifications that attempt to capture the most relevant dynamical properties of the system. In structural engineering, it is common to use the finite element method (FEM) to perform this kind of analysis [1]. In this case, the structure, which is essentially a continuous system, is idealized into a series of lumped masses interconnected by elements acting as springs and providing stiffness.

Using FEM, there are various methodologies that can be used to perform the dynamic analysis of a building against earthquake loading, such as explicit step-by-step integration of the coupled equations of motion [2], explicit step-by-step integration of the full (or a partial) set of uncoupled equations, response spectrum modal analysis (RSMA) [3] and the simplified equivalent lateral force (ELF) method [4]. Although RSMA and ELF are both approximate methods, they can give good results that can be used in engineering practice, especially if certain conditions are met. RSMA is widely used today as the standard procedure for designing earthquake resistant structures.

Both RSMA and ELF require the calculation of the natural periods (or eigenperiods) of the structure, i.e. the periods at which it will naturally resonate. These periods of vibration are very important in earthquake engineering and in structural dynamics in general. In structural design against earthquake loading, it is imperative that the natural frequency of the building does not match the frequency of expected earthquakes in the region the building is to be constructed. If the two frequencies match, resonance will occur, and the structure can experience severe damage. Determining the natural frequencies, or equivalently the eigenperiods of buildings, is of great importance in earthquake engineering.

The types of equations arising in FEM-based modal analysis are those seen in algebraic eigensystems. The physical interpretation of the eigenvalues and eigenvectors which come from solving the system is that they represent the frequencies and the corresponding mode shapes of the structure. In practical applications, the main desired modes are the lowest frequencies (or highest eigenperiods) because they represent the most prominent modes at which the structure will vibrate, dominating all higher frequency modes. In other words, the first (greatest) eigenperiods are the most important for determining the dynamic response of a structure. The ELF method is particularly based on the very first eigenperiod and the corresponding first eigenmode, only, while RSMA usually takes into account a limited number of eigenperiods and eigenmodes.

ANNs have been successfully employed in the structural engineering field to replace complex and time-consuming mathematical procedures and give predictions of analysis results, among others. Plevris and Asteris [5, 6] proposed a novel method with applying ANNs to approximate the failure surface for brittle anisotropic materials. Afaq et al. [7] created a novel knowledge-based structural analysis system based on ANN to predict the load-carrying capacity of RC members, reducing substantially the computational time compared to traditional Nonlinear finite element analysis. ANNs have also been used for the dynamic analysis of structures. Oh et al. [8] proposed a model to predict the seismic response of buildings based on the correlation of the ground motion and the structure using ANN. Worden and Green [9] developed a machine learning approach for the inversion of the modal transformation in nonlinear modal analysis. Gu and Oyadiji [10] presented an innovative approach using diagonal recurrent neural networks for the control of vibration in structural systems overperforming conventional control strategies such as the linear quadratic regulator for linear MDOF systems.

Bojórquez et. al [11] employed a Neural Network approach to obtain the transformation factors from single-degree of freedom (SDOF) to multi-degree of freedom (MDOF) to predict the seismic response of steel framed buildings, reducing considerably the computational effort. Payán-Serrano et al. [12] investigated the prediction of maximum story drift of MDOF structures subjected to dynamic wind load using ANNs through the combination of several structural and turbulent wind parameters. Chakraverty et al. [13] used ANNs to simulate and estimate the structural response of a two-story shear building by training the model for a particular earthquake. Lagaros and Papadrakakis [14] proposed a new adaptive scheme to predict the structural non-linear behavior when earthquake actions of increased severity are considered.

In this paper, a methodology is developed to replace the numerical procedure used for the calculation of the eigenperiods of MDOF shear buildings with an Artificial Neural Network (ANN). Two models with 3 and 5 stories are examined, where the mass and the stiffness are held constant for every story. For every model, a database with the solution of several idealized models with varying mass ( $m$ ) and stiffness ( $k$ ) is created using a number of ( $m, k$ ) pairs. Finally, an ANN is trained with the database to predict the eigenperiods of other similar models avoiding the direct computation of the eigenvalue problem. The remaining of this paper is organized as follows: In Section 2, a brief description of dynamic modal analysis is given with the definitions of SDOF and MDOF systems and the relevant equations. In section 3, the concept of ANNs for regression problems is explained, together with the introduction of some error metrics that can be used for NN predictions. Section 4 presents the methodology and the numerical results followed by section 5 where the conclusions and future research directions are discussed.

## 2 DYNAMIC MODAL ANALYSIS

Modal analysis is based on using the mass and stiffness of a structure to find the various periods at which it will naturally resonate. The RSMA method requires the calculation of the natural mode shapes and frequencies of a structure during free vibration as the method is based on the superposition of the responses of the structure and the use of a response spectrum. Instead of solving the time history problem for each mode, the method uses the response spectrum to compute the maximum response in each mode. Then the maximum modal responses are combined using some statistical technique, such as square root of the sum of the squares (SRSS) or complete quadratic combination (CQC).

### 2.1 Single-degree of Freedom System

An idealized shear building resulting in a SDOF system is depicted in Figure 1, where  $m$  is the mass of the system and  $k$  is its stiffness, provided by the column(s).

Figure 1: A SDOF dynamic system.

The dynamic equilibrium of the system at any instant of time  $t$  can be expressed as follows:

$$m\ddot{u}(t) + c\dot{u}(t) + ku(t) = F(t) \quad (1)$$

where  $\ddot{u}$ ,  $\dot{u}$  and  $u$  are the acceleration, velocity, and displacement, respectively,  $c$  is the damping of the system and  $F$  is the externally imposed dynamic loading. Eq. (1) is referred as the equation of motion and its solution is a well-known problem that has been studied thoroughly by many authors [15]. For a SDOF system without damping ( $c=0$ ), the circular frequency  $\omega$  of the system is given by the formula

$$\omega = \sqrt{\frac{k}{m}} \quad (2)$$

The cyclic frequency  $f$  is given by

$$f = \frac{\omega}{2\pi} \quad (3)$$

and the natural period of vibration, or eigenperiod  $T$ , is given by

$$T = \frac{1}{f} = \frac{2\pi}{\omega} = 2\pi\sqrt{\frac{m}{k}} \quad (4)$$

## 2.2 Multi-degree of Freedom System

The number of degrees of freedom for a vibrating system depends on the number of inertial elements (masses or rigid bodies) and the number of constraints imposed on the motion. A shear building idealized into a MDOF system with 3 degrees of freedom is depicted in Figure 2.

Figure 2: A MDOF dynamic system with 3 degrees of freedom (shear building).

The dynamic equilibrium of a MDOF structure at any instant of time  $t$  can be expressed with the following equation of motion:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{F}(t) \quad (5)$$

where  $\mathbf{M}$  is the mass matrix;  $\mathbf{K}$  is the stiffness matrix;  $\mathbf{C}$  represents the damping matrix,  $\ddot{\mathbf{u}}$ ,  $\dot{\mathbf{u}}$  and  $\mathbf{u}$  are the acceleration, velocity and displacement vectors, respectively, and  $\mathbf{F}$  is the external force vector.

In the case of free vibration without damping, Eq. (5) becomes

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{0} \quad (6)$$

In free vibration without damping, the system will oscillate in a steady-state harmonic manner. The resulting motion will be a mixture of modes, each having its own circular frequency  $\omega_i$  so that

$$\ddot{\mathbf{u}}(t) = -\omega_i^2 \mathbf{u}(t) \quad (7)$$

By substituting Eq. (7) on Eq. (6), the following expression is obtained

$$(\mathbf{K} - \omega_i^2 \mathbf{M}) \cdot \mathbf{u}(t) = \mathbf{0} \quad (8)$$

The  $n$  circular frequencies  $\omega_i$  ( $i=1, 2, \dots, n$ ) of the system can be found using Eq. (8), where the trivial solution is obtained when  $\mathbf{u}(t)=\mathbf{0}$ . For a non-trivial solution, the term inside the first parenthesis in Eq. (8) must be equal to zero, such that

$$|\mathbf{K} - \omega_i^2 \mathbf{M}| = 0 \quad (9)$$

After having found the circular frequencies  $\omega_i$ , we can now substitute those values back into Eq. (8) and solve for the vector  $\mathbf{u}$  which corresponds to the  $i$ -th modal shape. Each modal shape or eigenvector is denoted as  $\Phi_i$  ( $n \times 1$ ) so that Eq. (8) can be rewritten as

$$(\mathbf{K} - \omega_i^2 \mathbf{M}) \cdot \Phi_i = \mathbf{0} \quad (10)$$

Eq. (10) represents a classic problem in Mathematics referred as generalized eigenvalue problem [16] and its solution involves a series of matrix decompositions which can be computationally expensive, especially for large systems.

For the special case of a MDOF shear building with  $n$  degrees of freedom (stories), like the one of Figure 2 (shown there for the case  $n=3$ ), the mass matrix  $\mathbf{M}$  is a  $n \times n$  diagonal matrix given by

$$\mathbf{M} = \begin{bmatrix} m_1 & 0 & 0 & 0 \\ 0 & m_2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & m_n \end{bmatrix} \quad (11)$$

where  $m_i$  is the mass of every story starting numbering from the top to the bottom, according to the notation used in this manuscript. The stiffness matrix  $\mathbf{K}$  is a  $n \times n$  square matrix calculated as

$$\mathbf{K} = \begin{bmatrix} k_1 & -k_1 & 0 & 0 \\ -k_1 & k_1 + k_2 & -k_2 & 0 \\ 0 & -k_2 & \ddots & -k_{n-1} \\ 0 & 0 & -k_{n-1} & k_{n-1} + k_n \end{bmatrix} \quad (12)$$

where  $k_i$  is the stiffness of each story, with numbering again from top to bottom.

### 3 ARTIFICIAL NEURAL NETWORKS

An Artificial Neural Network is a collection of interconnected units referred as artificial neurons that resembles the basic structure of biological neurons that constitute animal and human brains. It is known that when a biological brain receives an input signal such as the desire to move a limb, the signal is processed through the interconnected neurons inside the brain to produce a corresponding output signal as a response [17]. In the case of moving a

limb, the response is a signal that contracts the required muscles to move it. The connectivity of the neurons inside the brain is the fundamental key to make that happen. Through the experiences of the individual, the connections of the neurons are constantly self-adjusting to improve the quality of the response. This process is what we, humans, know as learning.

An ANN tries to mimic the functionality of biological brains using an analogous but much more simplistic model. The ANN receives a set of numeric input values that are processed by the artificial neurons to produce a numeric response. To obtain the desired or “correct” response, the ANN is trained with known data containing numerous examples of inputs with their matching output values. Then, by using a mathematical optimization algorithm, the network parameters are adjusted so that the ANN learns to map the inputs to their corresponding outputs. Therefore, a properly trained ANN can be used to accurately predict the output values of new inputs that were not used in the training data [18].

### 3.1 Back Propagation Neural Networks

For this study, the selected ANN type is a backpropagation neural network (BPNN). The BPNN is composed of several layers and each layer has a specific number of neurons. The neurons of the first layer are connected to the neurons of the second layer, which in turn are connected to the neurons of the third layer, and so on. The very first layer and the last layer are known as the input and output layers respectively, while the other layers are called “hidden layers”. The notation used to denote the layer composition is generally as follows:

$$N - H_1 - H_2 - \dots - H_{L-1} - M,$$

where  $N$  denotes the number of neurons in the input layer (number of inputs),  $H_i$  stands for the number of neurons in the  $i$ -th hidden layer,  $M$  is the number of neurons in the output layer, and  $L$  is the total number of layers, including the output layer but excluding the input layer. For example, a 2-3-3-2 BPNN consists of an input layer with 2 neuron, 2 hidden layers with 3 neurons each, and an output layer with 2 neurons, as shown in Figure 3.

Figure 3: A 2-3-3-2 BPNN.

To obtain the output values from the ANN, the input values are fed to the network by a feedforward process. It starts by setting the input values at the first layer  $N$ , and then, moving forward to the next layer, the values of all the neurons at that layer are computed. The process is repeated until the output layer  $M$  is reached and the output values are obtained. At each neuron, a weighted summation of the values coming from the other connected neurons and an additional bias neuron is performed, see Figure 4.

Figure 4: Detail of a single neuron connected to 3 other neurons from the previous layer. The picture shows the process on how the numerical output value is obtained in a neuron.

For the case of Figure 4, the operation can be written in matrix form as follows

$$z = \mathbf{W} \cdot \mathbf{p} + b \quad (13)$$

$$\mathbf{W} = \begin{bmatrix} w_1 & w_2 & w_3 \end{bmatrix} \quad (14)$$

$$\mathbf{p} = \begin{bmatrix} p_1 & p_2 & p_3 \end{bmatrix}^T \quad (15)$$

$$O = \sigma(z) = \sigma(\mathbf{W} \cdot \mathbf{p} + b) \quad (16)$$

where  $O$  is the output of the output neuron,  $\mathbf{p}$  is a column vector with the values of the neurons at the previous layer;  $\mathbf{W}$  is the weight row vector that connects this output neuron with the previous layer; and  $b$  is a bias neuron that is added to the weighted summation to form the input for the activation function  $\sigma$ .

Activation functions are used to add non-linearity into the neural network and to facilitate the training process in which the gradient of the model parameters is computed. Additionally, they help to restrict the neuron values to a certain limit providing stability to the network. Therefore, the activation functions are usually simple, continuous, and differentiable. Among the most commonly used are the Linear, ReLu and Sigmoid activation functions. Figure 5 presents the Relu and the Sigmoid activation functions.

Figure 5: ReLu (a) and Sigmoid (b) activation functions, plotted from -10 to 10.

### 3.2 Training Process

The training process consists of adjusting the initial random weights of the network to fit the given training data. The weight updating process starts by feeding a set of input values

through the network and obtaining the corresponding outputs. The obtained values are then compared with their known values from the training dataset and an error is estimated using a predefined error function. The idea is to determine the gradient or the rate of change of the error function with respect to the model parameters (i.e. all the weights). Thanks to the network architecture, the computation of the gradient is possible using a chain rule of partial derivatives with the known quantities. Then, by using the back propagation scheme, the gradients computed at the output neurons are propagated back through the hidden layers so that a gradient value is defined at each one of the weights in the model. Finally, the weights of the model are updated by a small quantity obtained by multiplying the gradients with a factor called *learning rate*. This weight-update scheme is an optimization method known as gradient decent (GD) which attempts to minimize the error function.

To properly train the BPNN, the full training dataset must be processed by the network multiple times. In other words, the weights must be updated with the GD scheme for every data point in the training set. Every time that the full training set has been processed with the GD scheme is called an Epoch. However, at every Epoch, the data must be fed in different order as it turns out that if the full training data is presented multiple times in a random order, the overall fluctuations of the gradient update path will average out and converge to a good solution. Such random reordering of the training dataset at every Epoch is known as stochastic gradient decent (SGD) and it is one of the most popular weight-optimization schemes for ANNs.

The training process can be quite demanding in terms of computational effort for large NN models with large training data sets. Nevertheless, in this paper that is not the case as the investigated problem can be solved with a relatively simple BPNN architecture and a small amount of training data. The stopping criteria of the training process is usually monitored by having a separated validation set of data which is not used for training. At every Epoch, the error of both the training and the validation sets are measured. Naturally, the error of the training set reduces with every Epoch due to the optimization scheme. However, if the error on the validation set suddenly starts to increase, while the training set error keeps reducing, it is a clear indication of an unwanted characteristic called overfitting in which the NN loses its generality. Therefore, the stopping criteria is set to the last Epoch before the overfitting was detected. Alternatively, the stopping criterion can be set for a fixed number of Epochs.

### 3.3 Prediction error metrics

The NN predictions are never completely accurate as each prediction always contains a small error. There are various metrics that can be used to measure the prediction error. Let  $\mathbf{p}$  ( $N \times 1$  vector) be the predicted values and  $\mathbf{x}$  ( $N \times 1$  vector) be the real values of a quantity calculated (or measured) a number  $N$  of times. For example, for predicting the fundamental period of a MDOF system, we ask the NN to predict it  $N$  times using different pairs of  $m$  and  $k$  parameters. The following metrics can be defined for calculating the prediction error.

The prediction error values **Err** (or residuals) can be expressed as the difference between the predicted values and the real values, as follows:

$$\mathbf{Err} = \mathbf{p} - \mathbf{x} \quad (17)$$

The absolute value of the residuals (or absolute error) **AbsErr** is a measure of how far from the regression line data points are. Each element  $AbsErr_i$  of the vector **AbsErr** is given by

$$AbsErr_i = |Err_i| = |p_i - x_i| \quad (18)$$

The mean absolute error (**MAE**) is the average value of the absolute error, given as

$$MAE = \frac{\sum_{i=1}^N AbsErr_i}{N} = \frac{\sum_{i=1}^N |p_i - x_i|}{N} \quad (19)$$

The squared error **SqErr** is the squared value of the error, with its elements given by

$$SqErr_i = (p_i - x_i)^2 \quad (20)$$

The mean squared error (**MSE**) is the average value of the squared errors, given by

$$MSE = \frac{1}{N} \sum_{i=1}^N SqErr_i = \frac{1}{N} \sum_{i=1}^N (p_i - x_i)^2 \quad (21)$$

The root mean squared error (**RMSE**) is the square root of **MSE**, given by

$$RMSE = \sqrt{MSE} \quad (22)$$

The relative error values **RelErr** is the absolute error divided by the real value, provided that the real value is not equal to zero. It is given by

$$RelErr_i = \frac{|Err_i|}{x_i} = \frac{|p_i - x_i|}{x_i} \quad (23)$$

The mean relative error (**MRE**) is the average value of the relative errors, given by

$$MRE = \frac{1}{N} \sum_{i=1}^N RelErr_i = \frac{1}{N} \sum_{i=1}^N \frac{|p_i - x_i|}{x_i} \quad (24)$$

The Pearson correlation coefficient (**R**) is a measure of linear correlation between two sets of data, in our case the predicted values and the real values. It is the covariance of two variables, divided by the product of their standard deviations. Thus, it is essentially a normalized measurement of the covariance, such that the result always has a value between  $-1$  and  $1$ . If there is no error in the prediction, then the predicted values coincide with the real values and  $R=1$ . **R** is given by the formula

$$R = \frac{\sum_{i=1}^N (p_i - \bar{p})(x_i - \bar{x})}{\sqrt{\sum_{i=1}^N (p_i - \bar{p})^2} \sqrt{\sum_{i=1}^N (x_i - \bar{x})^2}} \quad (25)$$

In the above formula,  $\bar{p}$  and  $\bar{x}$  are the mean values of **p** and **x**, respectively:

$$\bar{p} = \frac{1}{N} \sum_{i=1}^N p_i \quad (26)$$

$$\bar{x} = \frac{1}{N} \sum_{i=1}^N x_i \quad (27)$$

## 4 NUMERICAL RESULTS

Two models have been examined, a 3-DOF shear building and a 5-DOF shear building. For both models, the parameters *m* (mass) and *k* (stiffness) are the same for all stories, as shown in Figure 6. This limits the input parameters of the Neural Network to 2 in every case.

The output parameters are the eigenperiods of the system, which are 3 for the 3-DOF system and 5 for the 5-DOF system. The mass  $m$  varies from  $m_{\min}=2$  ton to  $m_{\max}=20$  ton while the stiffness  $k$  varies from  $k_{\min}=20,000$  kN/m to  $k_{\max}=200,000$  kN/m.

We use standard intervals of  $m$  and  $k$  for the generation of the data used for training. The mass and stiffness intervals are set to 6, which means that we have 7 values of mass and 7 values of stiffness which makes  $7 \times 7 = 49$  pairs of  $(m, k)$  for each structure. 70% of the database is used for training (35 pairs), while the rest (30%) of the database is used for validation (15%, 7 pairs) and testing (15%, 7 pairs).

For both cases, we use a simple NN architecture of one hidden layer with 10 neurons. In the 3-DOF system, the network architecture is 2-10-3 while for the 5-DOF system, the network architecture is 2-10-5.

Figure 6: (a) 3-DOF shear building, (b) 5-DOF shear building.

#### 4.1 Three DOF system

The first numerical example is a 3-DOF system where the NN is asked to predict the three eigenperiods of the system, i.e.  $T_1, T_2, T_3$  where  $T_1 > T_2 > T_3$ . The NN architecture used is 2-10-3. The maximum number of validation increases is set to 6, i.e. if the error in the validation set increases for 6 times then the training is stopped. Given this criterion, training is stopped in Epoch 110, as shown in Figure 7.

Figure 7: Example 1, Final NN Train State.

The performance of the NN is depicted in Figure 8, where the three lines show the error obtained for the training set (blue line), the validation set (green line) and the test set (red line).

Figure 8: Example 1, NN Training Performance.

The training regression of the NN data is depicted in Figure 8, where the three colored lines correspond again to the three different sets and the fourth black line contains all the data sets together. The  $R$  values reported correspond to the normalized data.

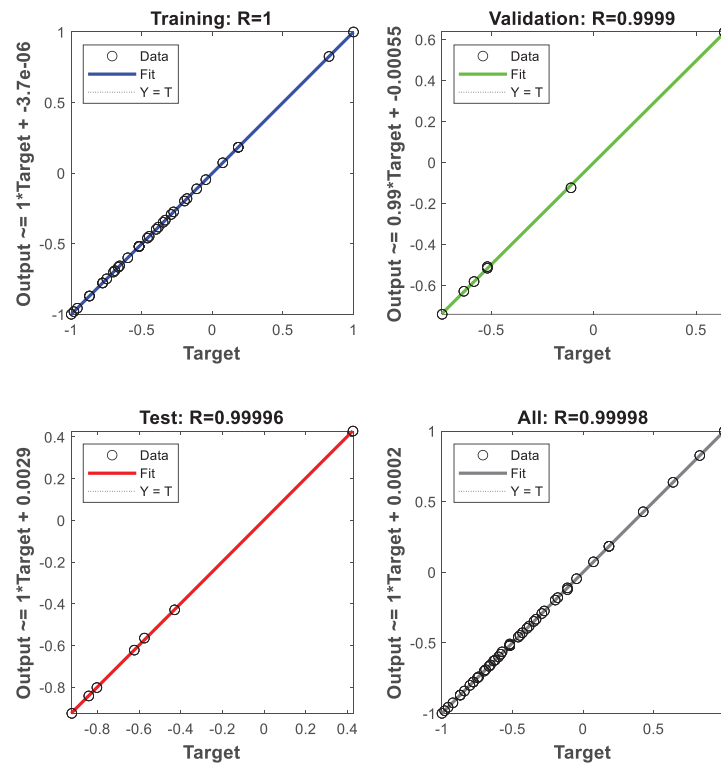

Figure 9: Example 1, NN Training Regression (for the Normalized Data).

Figure 10: Example 1, NN Error Histogram (for the Normalized Data).

In order to test the NN results, we generated 100 random  $(m, k)$  pairs within the training region and we calculated the errors in the NN predictions. The results are presented in Table 1.

<b>Metric</b>	<b><math>T_1</math></b>	<b><math>T_2</math></b>	<b><math>T_3</math></b>	<b>All periods</b>
<i>MSE</i>	4.33E-06	5.52E-07	2.64E-07	1.72E-06
<i>RMSE</i>	2.08E-03	7.43E-04	5.14E-04	1.31E-03
<i>MAE</i>	8.46E-04	3.02E-04	2.09E-04	4.52E-04
<i>MRE</i>	4.10E-03	4.10E-03	4.10E-03	4.10E-03
<i>R</i>	0.999745	0.999745	0.999745	0.99986

Table 1: Example 1, Error metrics for the independent test with 100 random  $(m, k)$  pairs..

It is shown that the error of the NN predictions is very small. The mean relative error is only 0.41% for all the NN predictions together ( $T_1$ ,  $T_2$  and  $T_3$ ). As an example, for  $m=5.52$  ton and  $k=137,000$  kN/m, the real values of the eigenperiods are  $T_1=0.0896$  s,  $T_2=0.0320$  s and  $T_3=0.0221$  s, as shown in Figure 11 together with the three corresponding eigenmodes. The corresponding NN predictions are  $T_1=0.0898$  s,  $T_2=0.0320$  s and  $T_3=0.0222$  s. The NN manages to give very accurate results, although the data set used contains only 49  $(m, k)$  pairs, of which only 35 (70%) have been used for the NN training itself.

Figure 11: Eigenmodes of a 3-DOF shear building with  $m=5.52$  ton and  $k=137,000$  kN/m (uniformly, at every story).

#### 4.2 Five DOF system

The second numerical example is a 5-DOF system where the NN is asked to predict the five eigenperiods of the system, i.e.  $T_1$  to  $T_5$ , where  $T_1 > T_2 > T_3 > T_4 > T_5$ . The NN architecture used is 2-10-5, with 10 neurons in the hidden layer. The maximum number of validation increases is again set to 6. This time training stops earlier, in Epoch 30, as shown in Figure 12.

Figure 12: Example 2, Final NN Train State.

The performance of the NN is depicted in Figure 13, where the three lines show the error obtained for the training set (blue line), the validation set (green line) and the test set (red line).

Figure 13: Example 2, NN Training Performance.

The training regression of the NN data is depicted in Figure 14, where the three colored lines correspond again to the three different sets and the fourth black line contains all the data sets together. The  $R$  values reported correspond to the normalized data.

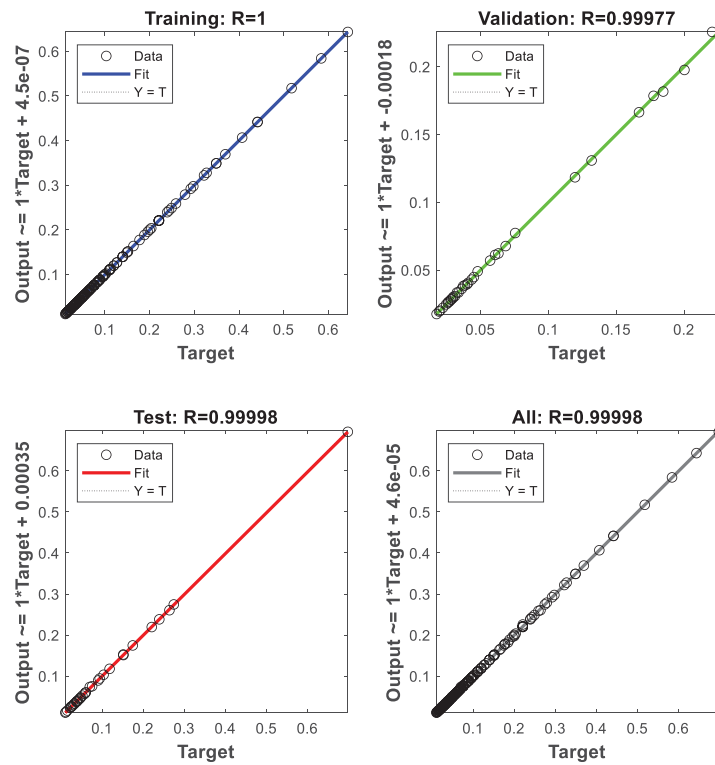

Figure 14: Example 2, NN Training Regression (for the Normalized Data).

Figure 15: Example 2, NN Error Histogram (for the Normalized Data).

In order to test the NN results, we generated 100 random  $(m, k)$  pairs within the training region and we calculated the errors in the NN predictions. The results are presented in Table 1.

Metric	$T_1$	$T_2$	$T_3$	$T_4$	$T_5$	All periods
$MSE$	1.52E-05	1.78E-06	7.18E-07	4.35E-07	3.34E-07	3.69E-06
$RMSE$	3.90E-03	1.34E-03	8.47E-04	6.60E-04	5.78E-04	1.92E-03
$MAE$	2.02E-03	6.94E-04	4.40E-04	3.43E-04	3.00E-04	7.60E-04
$MRE$	7.95E-03	7.95E-03	7.95E-03	7.95E-03	7.95E-03	7.95E-03
$R$	0.999678	0.999678	0.999678	0.999678	0.999678	0.999859

Table 2: Example 2, Error metrics for the independent test with 100 random  $(m, k)$  pairs.

It is shown that the error of the NN predictions is again very small. The mean relative error is only 0.79% for all the NN predictions together ( $T_1$  to  $T_5$ ). As an example, for  $m=5.52$  ton and  $k=137,000$  kN/m, the real values of the eigenperiods are  $T_1=0.1401$  s,  $T_2=0.0480$  s,  $T_3=0.0305$  s,  $T_4=0.0237$  s,  $T_5=0.0208$  s, as shown in Figure 16. The corresponding NN predictions are  $T_1=0.1384$  s,  $T_2=0.0474$  s,  $T_3=0.0301$  s,  $T_4=0.0234$  s,  $T_5=0.0205$  s. The NN manages to give very accurate results for all five eigenperiods.

Figure 16: Eigenmodes of a 5-DOF shear building with  $m=5.52$  ton and  $k=137,000$  kN/m (uniformly, at every story).

## 5 CONCLUSIONS

In the present study, a methodology to predict the dynamic properties of a MDOF idealized model using a machine learning oriented strategy is implemented. An Artificial Neural Network is trained to accurately predict all the eigenperiods of MDOF shear buildings with a uniform distribution of mass and stiffness at every story. The goal of the study has been to reduce the computational effort of the complex mathematical process that is required to solve the generalized eigenvalue problem that arises from the modal analysis. It is noted that to train the ANN, a training database of previously solved eigenvalue problems is required, which is itself also a computationally expensive operation. However, the creating of the training set and the

training procedure are one-time processes, only. After the ANN is trained, it can be used to predict the behavior of any system (within the domain of the training data) with a very low computational effort.

The methodology has been tested for two different MDOF models, a 3-DOF system and a 5-DOF system. The results show highly accurate predictions reaching mean relative error values of 0.41% and 0.79%, respectively. All the error metrics used show a highly accurate prediction. This research has shown that for this type of problems, a relatively small database can be used to train highly accurate BPNNs. The developed framework is going to serve as a base for further research into more complex dynamic systems, for example systems with more degrees of freedom and also multi-story shear buildings with independent values of  $m$  and  $k$  for every single story. Having independent values of mass and stiffness at each story dramatically increases the complexity of the problem as the input parameters increase from 2 to  $3 \times 2 = 6$  and  $5 \times 2 = 10$  for the 3-DOF and the 5-DOF system, respectively.

### Abstract

*Over the years, the buckling restrained braces (BRBs) have more and more become one of the best solutions for retrofitting or upgrading many existing reinforced concrete framed buildings located in areas with a high seismic hazard. The present investigation studies the effectiveness of BRBs used to seismically retrofit a reinforced concrete (RC) building in L'Aquila defining an advanced non-linear 3D model in OpenSees. The seismic performance of the investigated building is assessed developing the following comparisons: before and after the retrofit through BRBs. Adopting a hysteretic model specific for the BRBs, both non-linear static analyses and incremental dynamic analyses under a set of real ground motion records are carried out to build the seismic demand hazard curves. The numerical results highlighted the influence of the BRBs on the seismic performance of the system components also in relation to the effectiveness of the retrofit.*

## 1 INTRODUCTION

Among the different solutions available to enhance the performance of existing structures, a great variety of passive energy dissipation systems [1]-[3] have been proposed in the last decades. These systems are usually classified as hysteretic dampers, viscoelastic dampers, viscous fluid dampers [4] and friction dampers [5]. Buckling restrained braces (BRBs) are hysteretic dampers that constitute one of the most efficient system for adding stiffness, strength and energy dissipation capacity to a structure [6]-[8]. The effectiveness of these devices has been proven by many experimental tests and numerical simulations, and numerous applications to existing buildings have been documented in the literature (e.g., [9]-[12]). BRBs consist of a steel core placed inside a steel tube filled with a concrete material [13]-[14]. According to numerous experimental tests, BRBs exhibit a stable hysteretic behaviour with a high-energy dissipation capacity, up to ductility levels higher than 20 [15]-[16].

Many studies in the literature have proposed methodologies for the design of BRBs for retrofitting existing frames and have evaluated the performance of the retrofit with deterministic approaches (e.g., [17]-[19]). However, very few works have analyzed the performance of buildings retrofitted with BRBs by employing probabilistic approaches accounting for the effect of the uncertainties inherent to the seismic input. Among these, Guneyisi [20] investigated the application of BRBs for seismic retrofitting of steel moment resisting framed buildings. Fragility curves were developed using the maximum interstorey drift ratio as engineering demand parameter (EDP), and were used to compare the performances of the bare frame, the frame retrofitted with conventional braces, and the frame retrofitted with BRBs. Freddi et al. [7] proposed a probabilistic framework, based on the use of component and system fragility curves, to evaluate the effectiveness of BRBs for retrofitting reinforced concrete (RC) frames with low ductility capacity. Moreover, important EDPs, such as the absolute accelerations, were disregarded. Adding stiffness and strength to a frame through the BRBs often leads to an increase rather than a decrease of absolute accelerations, due to the reduction of the vibration period, and this may affect the performance of acceleration-sensitive non-structural building components. Furthermore, it is widely acknowledged that the main drawback of BRBs is their low post-yield stiffness, which may result in excessive residual inter-storey drifts in structures equipped with them [21]-[23]. Thus, an assessment of the effectiveness of the retrofit should also account for the response in terms of these two EDPs.

Finally, previous studies on the performance of buildings retrofitted with BRBs have employed simplified models of the BRBs with essentially elasto-plastic behaviour and kinematic hardening. However, more sophisticated constitutive models should be considered to properly account for the specific features of the behaviour of these devices that emerged in numerous experimental tests [13], [24]-[25]. These include the significant role of isotropic hardening and the asymmetry in the yield force in compression with respect to that in tension [13], [24]. The cumulative plastic deformations in the BRBs, that may control the failure of these devices due to low-cycle fatigue, need also to be monitored [26]-[31].

The aim of this work is to evaluate the effectiveness of buckling restrained braces for retrofitting an existing RC building, by employing an advanced model of BRBs and a wide range of EDPs for monitoring the performance of the building components and of the BRBs. For this purpose, an existing RC building located in L'Aquila, damaged by the 2009 earthquake, is used as case study. First, a non-linear three-dimensional model of the existing RC building is defined in OpenSees [32]. A widely employed procedure based on pushover analyses and N2 method [33] is employed to design the braces. Specifically, the bracing system is designed by disregarding the effect of infill walls and with the target objective of achieving a maximum interstorey drift ratio of 1.5% under the life safety limit state design seismic action [34] for the

site (return period of 475 years). Successively, the seismic performance of the retrofitted building is evaluated by performing both non-linear static analyses and incremental dynamic analyses under a set of real ground motion records. Seismic fragility and demand hazard curves of the building are derived considering multiple EDPs. These include the maximum interstorey drifts together with the absolute accelerations.

The capability of the dissipative bracing system in enhancing the performance of structural and non-structural components of the frame is assessed by evaluating the results in terms of seismic demand hazard curves, providing the annual rate exceeding different demand levels.

## 2 CASE STUDY: DESCRIPTION AND MODELLING

The case study (Figure 1) is a reinforced concrete frame built in 1984 that is representative of many RC structures built in Italy before the introduction of modern seismic codes and designed for gravity loads only, without any seismic detailing. The building is composed of five stories with a height of 2.8 m at the ground storey and of 3 m at the other storeys. Figure 1 describes the plan configuration of the frame, with an overall length of 25.30x10.85 m along the horizontal (X) and vertical (Y) directions, respectively. A reinforced concrete staircase is located centrally in the lower part of the building. The frame columns have a rectangular cross section with dimensions 35x60 cm at the ground floor and 30x60 cm at the other floors, whereas the columns that support the stair landing have the same rectangular cross section of 25x60 cm at each floor. The beams along the Y direction are deep beams with various rectangular sections: 35x50 cm, 30x50 cm and 25x50 cm. The properties of materials used for the structural components of the frame have been evaluated via a campaign of destructive in-situ tests. In particular, the concrete material behavior was evaluated based on 16 compressive tests on concrete cores extracted from the RC frame elements, while the steel properties were evaluated based on tensile strength tests executed on rebar samples. Table 1 reports the average mechanical properties for unconfined concrete and reinforcement steel. With regards to concrete,  $f_c$  denotes the compressive strength,  $E_c$  the elastic modulus,  $\varepsilon_c$  and  $\varepsilon_{cu}$  the peak and ultimate deformations, and  $f_{cu}$  the ultimate strength. With regards to steel,  $f_{sy}$  is the yield stress,  $E_s$  the elastic modulus, and  $b$  the post-elastic to elastic stiffness hardening ratio.

Figure 1. Schematic plan configuration of the building. (Dimensions in cm)

Unconfined concrete					Steel		
$f_{cm}$ [N/mm <sup>2</sup> ]	$\varepsilon_c$ [-]	$f_{cu}$ [N/mm <sup>2</sup> ]	$\varepsilon_{cu}$ [N/mm <sup>2</sup> ]	$E_c$ [N/mm <sup>2</sup> ]	$f_{sy}$ [N/mm <sup>2</sup> ]	$E_s$ [N/mm <sup>2</sup> ]	$b$ [-]
21.6	0.018	21.6	0.0035	27717.8	430.7	206000	0.01

Table 1. Mechanical properties of unconfined concrete and steel reinforcement.

The building is located in L'Aquila (Italy), with geographical coordinates Lon. = 13.394° and Lat. = 42.36°, on a soil of class D and topographical category T1, according to [34]. Figure 2 shows the code elastic response spectra in terms of accelerations and displacements for different limit states and relevant return periods (i.e., Operational – 30 years, Damage – 50 years, Life Safety – 475 years, Near Collapse - 975 years) assuming an inherent damping factor of 5%, respectively.

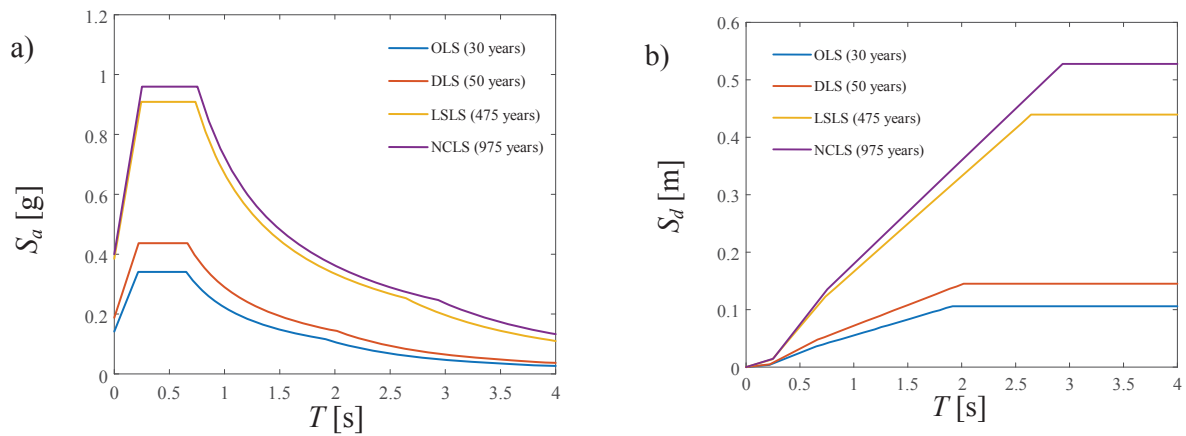

Figure 2. Code elastic response spectra in terms of accelerations a) and displacements b).

Figure 3 shows the numerical model of the RC frame developed in OpenSees [32], which employs “beam with hinges” elements [35] to describe the nonlinear hysteretic response of beams and columns. The beam-column joints are described by beam elements with very high stiffness whereas the in-plane rigid floor slab is described by a diaphragm constraint at each floor. In the “beam with hinges” elements, the inelastic behaviour is concentrated over specified hinge lengths  $L_{pi}$  and  $L_{pj}$  at the two element ends while, a linear elastic behaviour is assigned to the central portion. The lengths of the plastic hinges are defined as a function of the shear span  $L_v$ , assumed equal to the half element length, and of the product between the bar yield strength and diameter  $f_{sy}d_b$  [36]:

$$L_p = 0.12L_v + 0.014\alpha_{sl}f_{sy}d_b \quad (1)$$

where  $\alpha_{sl}$  is a variable that can assume the value 1 if the slippage of the reinforcement bars from the anchorage zone beyond the end section is possible or 0 if is not.

In the plastic hinge zone, the behaviour of concrete is described by the nonlinear degrading Concrete02 material model [32], with tensile strength set to  $0.1f_{cm}$  and a linear tension softening.

The effect of the confinement of the concrete core fibers of beams and columns is taken into account by modifying the concrete constitutive law as suggested by [37]. The compressive

strength of the confined concrete increases thanks to the compressive effect provided by the stirrups and the longitudinal reinforcement and can be evaluated as:

$$f'_{cc} = f_{cm} \left( -1.254 + 2.254 \sqrt{1 + \frac{7.94 f'_l}{f_{cm}}} - 2 \frac{f'_l}{f_{cm}} \right) \quad (2)$$

where  $f_{cm}$  is the compressive strength of the unconfined concrete (Table 1) and  $f'_l$  depends on the geometry of the section and of the reinforcements as explained in [37]. The ultimate compressive strain,  $\varepsilon_{cu}$ , corresponds to the rupture of the first hoop and can be found based on an energy balance approach [37]. The confinement differs for each section, since it depends on the dimensions, and amount of longitudinal bars and stirrups. Thus, different values of  $f'_{cc}$ , crushing strength and  $\varepsilon_{cu}$  are obtained for the various sections.

The behaviour of steel reinforcement is described by using a uniaxial bilinear constitutive law with kinematic hardening (Steel01 in OpenSees [32]). Concrete cracking is taken into account by considering an effective flexural stiffness for the elastic part of each beam and column element. This stiffness is evaluated by means of moment-curvature analysis of the sections at the extremes of the elements, for the axial force level induced by the dead loads (zero axial load in case of beams).

Figure 3. Numerical model of the RC building in OpenSees (with no infills).

Using the function “MinMax material” of OpenSees [32], material failure can be simulated in the fibers of the RC sections by setting the stresses to zero once a prefixed strain threshold value is attained. Conservatively, the same threshold of  $\varepsilon_{cu}$  equal to -0.012 is set for all the concrete fibers with the confined properties. For the unconfined concrete of the cover of the cross sections, the strain threshold was set to -0.0035. The rupture of the reinforcement bars, with a drop of the stress to zero, is assumed to occur at a strain of 0.075. The system nonlinear geometrical behaviour is taken into account by considering second-order P-delta effects.

### 3 DESIGN AND MODELLING OF THE HYSTERETIC DEVICES (BRBS)

The method proposed by Dall'Asta et al. [17] is employed in this study to design the dissipative bracing system. According to this method, the dissipative bracing system and the existing frame are described as two elastic-perfectly plastic single-degree-of-freedom (SDOF) systems acting in parallel. The properties of the SDOF system equivalent to the existing frame

are derived by performing a pushover analysis under a distribution of forces corresponding to its first vibration mode [33]. The capacity curve of the frame is replaced by an elastic perfectly-plastic one, which is obtained based on an energy equivalence criterion and is described by the initial stiffness  $K_f$ , the base shear capacity  $V_f$ , and the ductility capacity  $\mu_{fc}$  (Figure 4a).

The properties of the bracing system depend on the properties of the diagonal braces at each storey. It is worth to recall that the diagonal dissipative braces considered here consist of two members in series, namely the BRB device and the over-strengthened brace. Only the first one undergoes plastic deformations, whereas the second is designed to remain elastic.

The distribution of the stiffness of the braces along the building height is assumed equal to the one of the frame in order to obtain a coupled system with the same first mode shape. Moreover, the braces are assumed to yield simultaneously when the structure vibrates according to the first mode.

The design ultimate displacement of the diagonal brace system can be assumed equal to that of the frame, in order to ensure simultaneous failure of both the frame and the braces. The capacity curve of the bracing system is idealized as an elastic-perfectly plastic curve, and described by few parameters that are the design variables: the initial stiffness  $K_d$ , the base shear capacity  $V_d$ , and ductility capacity  $\mu_{dc}$ , equal to that of the diagonal braces under the assumption of simultaneous yielding of the diagonal braces at all the storeys. It is noteworthy that the BRBs, and thus the bracing system, exhibit a more complicated behaviour, which however is simplified in the design stage.

In this study, only the retrofit of the frame along the X direction is considered, since this corresponds to the weak direction of the bare frame. The results from the modal analysis of the bare frame for the first five vibration modes are summarized in Table 2. The coupling between the modal responses along the two directions is very low, and the mass participation factor of the first mode along the X direction is very high (i.e., 80.8%).

Mode	Type	$\omega$ [rad/s]	$T$ [s]
1	Translational X	7.388	0.850
2	Rotational	9.371	0.670
3	Translational Y	9.496	0.662
4	Translational X	23.432	0.268
5	Rotational	30.300	0.207

Table 2. Vibration modes of the bare frame.

The design procedure of the bracing system requires the evaluation of the bare frame capacity curve along the X direction by means of a nonlinear static (pushover) analysis. The lateral load pattern for the pushover analysis is determined for a distribution of the loads proportional to the first vibration mode of the structure. The control node is the centre of mass of the top floor. Figure 4a shows the capacity curve of the equivalent SDOF system and its bilinearization according to the Italian code [34]. These curves are expressed in terms of  $d^*$  and  $V^*$ , which are obtained dividing the displacement of the control node and the base shear of the MDOF system by the modal participation factor  $\Gamma = \sum m_i u_i / \sum m_i u_i^2$  of the first vibration mode. The ductility capacity of the frame is  $\mu_{fc} = 3.73$ , corresponding to a maximum inter-storey drift ratio of 2.3%.

Figure 4b compares, in the acceleration-displacement plane, the elasto-plastic capacity curve of the bare frame and the seismic demand for the life safety limit state according to the N2 method. The values of the acceleration  $a^*$  of the capacity curve are obtained by dividing the forces  $V^*$  by the equivalent mass  $m^* = \sum m_i u_i$  of the SDOF system. It can be seen that the ductility demand  $\mu_f=3.55$  is quite close to the ductility capacity of the structure. Thus, the structure needs to undergo significant plastic deformations to withstand the seismic demand, leading to extended damage.

In order to reduce the seismic damage, the bracing system is added in parallel to the frame, and the target ductility demand of the frame under the design seismic input is assumed equal to  $\mu_f=2.64$ , corresponding to a maximum interstorey drift ratio (IDR) of 1.5%.

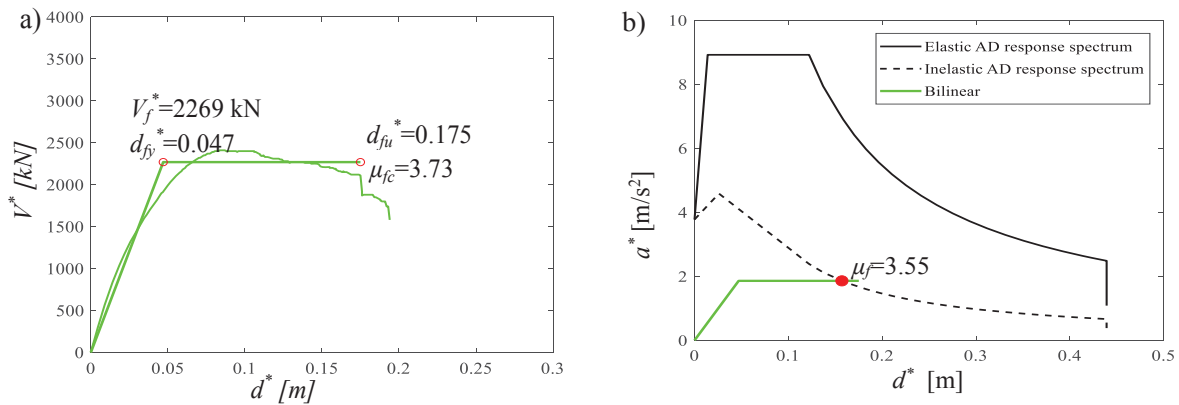

Figure 4. a) Capacity curve of the SDOF system equivalent to the bare frame and its bi-linearization and b) comparison between the seismic demand and capacity for the bare frame.

The ductility capacity of the BRB devices and of the dissipative system are assumed respectively equal to  $\mu_{0c}=15$  and  $\mu_{dc}=10$ . It is noteworthy that the value of  $\mu_{dc}$  is less than the value of  $\mu_{0c}$  due to the flexibility of the brace placed in series with the BRB device ([6], [17]). The base shear capacity of the BRB system must be equal to  $V_d=900$  kN to obtain a design capacity curve of the coupled system (frame and BRBs system) that intersects the inelastic demand spectrum (Figure 5a-b). It is noteworthy that the base shear of the bracing system is only 39% of the base shear of the bare frame. Although a higher value could be chosen, by reducing the ductility demand of the frame, this would result in excessive forces transmitted to the columns adjacent to the bracing system, and an increase of their vulnerability [6]. Moreover, higher values of this ratio are generally associated with excessive interstorey residual drift levels, impairing reparability after major earthquake events.

Given the properties of the bracing system, the characteristics of the BRB devices and of the elastic braces at each storey can be determined by following the procedure described in Dall'Asta et al. [17] and they are reported in Table 3. It is worth to recall that the design properties of the braces (initial stiffness  $K_d^i$ , yielding force  $F_d^i$  and ductility capacity  $\mu_{dc}^i$  where  $i$  denotes the storey number) depend on the properties of the BRB device (initial stiffness  $K_0^i$ , yield force  $F_0^i$  and ductility capacity  $\mu_{0c}^i$ ) and on the properties of the elastic brace (length  $L_b^i$  and stiffness  $K_b^i$ ). The brace length  $L_d^i$  is equal to the sum of the BRB length  $L_0^i$  and the elastic brace length  $L_b^i$ .

In order to limit the axial forces transmitted to the columns adjacent to the braces, four diagonal braces are employed at each storey. The brace arrangement is shown in Figure 6.

Table 3. Dissipative braces, BRBs and elastic brace properties at each storey.

Figure 6. Modelling of the BRB by means of two elements (truss + elastic beam).

The dissipative braces are modelled by using two elements (Figure 6): an elastic beam element for the elastic brace and a truss element for the BRB. The BRB is assigned the constitutive law of Zona et al. [30]. The parameters that influence the hardening and hysteresis of the elasto-plastic model can be calibrated based on experimental characterization tests carried out on BRB prototypes. In this study, the parameters reported in Zona et al. [30] and calibrated on

the experimental tests of Tremblay et al. [38] are considered. Figure 7 shows the capacity curve evaluated by performing the nonlinear static analysis of the retrofitted structure, and the corresponding equivalent bilinear curve. The capacity curve is truncated at a value of the displacement equal to 0.15 m, corresponding to an IDR of 1.5% for the frame and a ductility capacity  $\mu_c=3.22$ . The ductility of the coupled system is much higher than that of the frame ( $\mu_f=2.64$ ), thanks to the addition of the BRBs. Figure 7b compares the elastic and inelastic seismic demand with the capacity of the coupled system. The seismic design action induces a ductility demand of 3.13 (Figure 7b) in the system.

It is noteworthy that the design of the dissipative bracing system has been carried out disregarding the contribution of the infill walls.

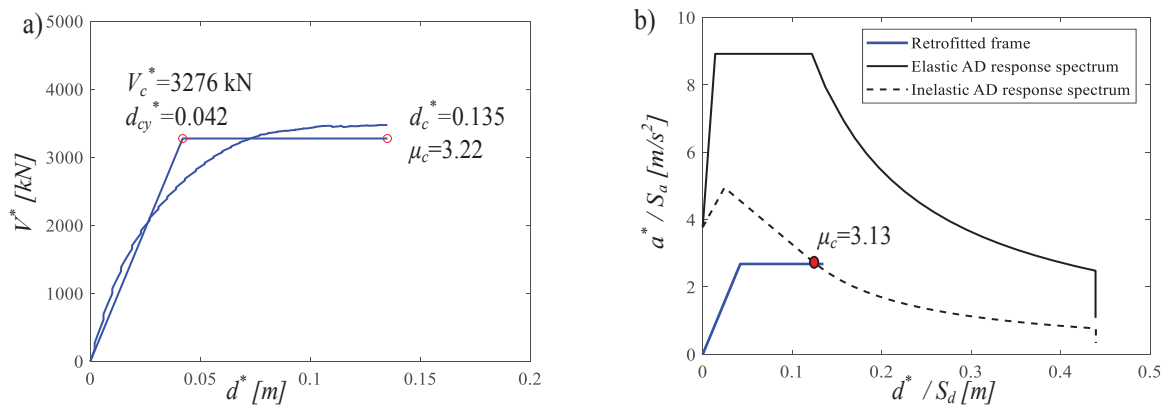

Figure 7. a) Capacity curve of the SDOF system equivalent to the retrofitted system and its bi-linearization and b) comparison between the seismic demand and capacity for the retrofitted frame.

#### 4 SEISMIC PERFORMANCE AND RETROFIT EFFECTIVENESS EVALUATION

The seismic performance assessment of the system and the evaluation of the effectiveness of BRBs for the retrofit are based on the development and comparison of seismic demand hazard curves for different EDPs describing the seismic response of structural and non-structural components, as well as of the BRBs. Coherently with the performance-based earthquake engineering (PBEE) approach [39]-[41], the uncertainties related to the seismic input intensity are separated from those related to the characteristics of the record (i.e., record-to-record variability) by introducing an intensity measure ( $IM$ ). In particular, the randomness in the seismic intensity is described by a hazard curve, whereas the record-to-record variability for a fixed intensity level is modelled by selecting a set of natural ground motion records characterized by a different duration and frequency content, scaled to the assumed intensity level [42].

It is worth to note that, in general, the  $IM$ 's choice should be driven by criteria of efficiency, sufficiency and hazard computability [43]-[45]. In this study, the spectral acceleration,  $S_a(\xi, T)$ , at the fundamental period of the system,  $T = 2\pi / \omega$  and for the damping ratio  $\xi = 5\%$ , is assumed as intensity measure. This is a structural dependent  $IM$  that changes with the structural model. Table 4 reports the periods of the four models considered, together with the corresponding  $IM$  values at the life safety limit state (LFLS) and near collapse limit state (CLS).

Incremental dynamic analysis (IDA) [46] are carried out to investigate the response of the different systems for increasing intensity levels. The set of 30 ground motion records employed in IDA are derived from 19 different seismic natural events, selected within the ground motion database of PEER (Pacific Earthquake Engineering Research Center) [47], of ITACA

(Italian Accelerometric Archive) [48] and of ISESD (Internet-Site for European Strong-Motion Data) [49]. The characteristics of the selected ground motion records are reported in Table 5. Their source-to-site distance,  $R_s$ , is greater than 8.7 km, and their moment magnitude,  $M$ , is in the range between 6 and 7.6. Figure 8 shows the acceleration elastic response spectra of the unscaled records of Table 5.

	Bare frame	Retrofitted frame	Infilled frame	Inf. retrofitted frame

Table 5. Selected ground motions for the time history analyses.

The EDPs considered for monitoring the seismic response are the peak values, among the various storeys, of the interstorey drift ratio (IDR) and the absolute acceleration (ACC).

Figure 8. Acceleration elastic response spectra for the seismic records. The dashed lines indicate the structural periods of the various models.

Figure 9 shows the IDA curves in terms of IDR obtained for the various models considered. It is noteworthy that for high  $IM$  values, some convergence issues arise due to the failure of some fibers in critical sections and nonlinear geometrical behaviour of the model. Thus, plotted in the figure are only the numerically-converging dynamic analysis points. It can be observed in the plot that in the case of the bare frame, the IDR of 1.5% is reached at an  $IM = 0.3g$  for the bare frame model and at  $0.7g$  for the retrofitted model. This results already shows the benefit of the use of the BRBs in terms of drift reduction, which is only partially impaired by the seismic demand increase due to period reduction (see Table 4).

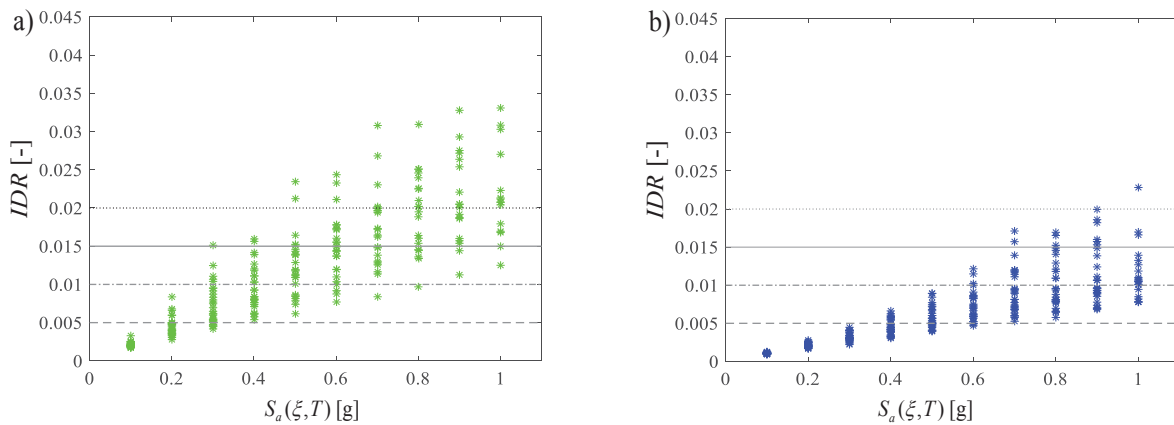

Figure 9. IDA results in terms of IDR: a) Bare frame; b) Bare frame with BRBs.

For each EDP considered, the conditional exceeding probability  $G_{EDP|IM}(d|im)$  is evaluated for the different models at the various  $IM$  levels considered. Both the collapse (and convergence) and not-collapse results are taken into account by applying the total probability theorem [50]-[53], according to the following expression:

$$G_{EDP|IM}(edp|im) = G_{EDP|IM}(edp|im, NC)(1 - P[C|IM]) + P[C|IM] \quad (3)$$

where  $G_{EDP|IM}(edp|im, NC)$  is the probability of exceedance of the EDP conditional to the  $IM$  and to not-collapse, the probability of collapse  $P[C|IM]$  is evaluated numerically for each  $IM$  level by dividing the number of analyses for which collapse occur by the total number of analyses.

Figure 10 shows the conditional exceedance curves for the IDRs, which are fitted by means of lognormal distributions. Five different demand thresholds are considered, namely 0.5%, 1%, 1.5%, 2% and 2.5%. These values correspond to increasing levels of seismic damage of the frame [50], [51], [54]. Obviously, the median value of the spectral acceleration corresponding to the threshold of 1.5% increases due to the retrofit and slightly decreases if the infill frames are considered in the models.

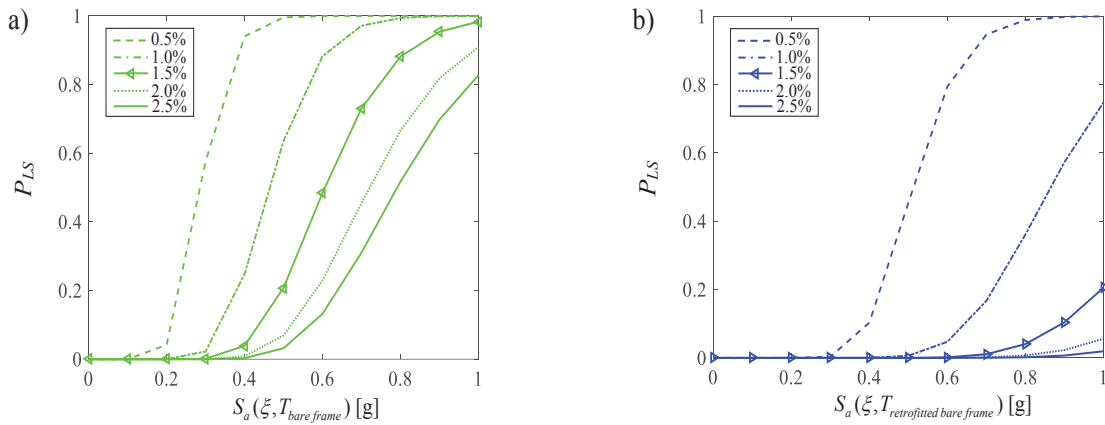

Figure 10. Conditional probability of exceedance vs. IM for the IDR: a) Bare frame; b) Bare frame with BRBs.

Figure 11 illustrates the conditional exceedance curves for the other EDP. In general, the exceeding probabilities decrease for increasing values of the threshold and increase for higher  $IM$  levels, as expected. The systems with added BRBs exhibit lower conditional probabilities compared to the ones without BRBs, for the same  $IM$  and threshold levels, for all the monitored EDPs. Quite interestingly, also the probability of exceedance of the absolute accelerations slightly reduces due to the addition of the BRBs, whereas the infills have a minor effect on this probability.

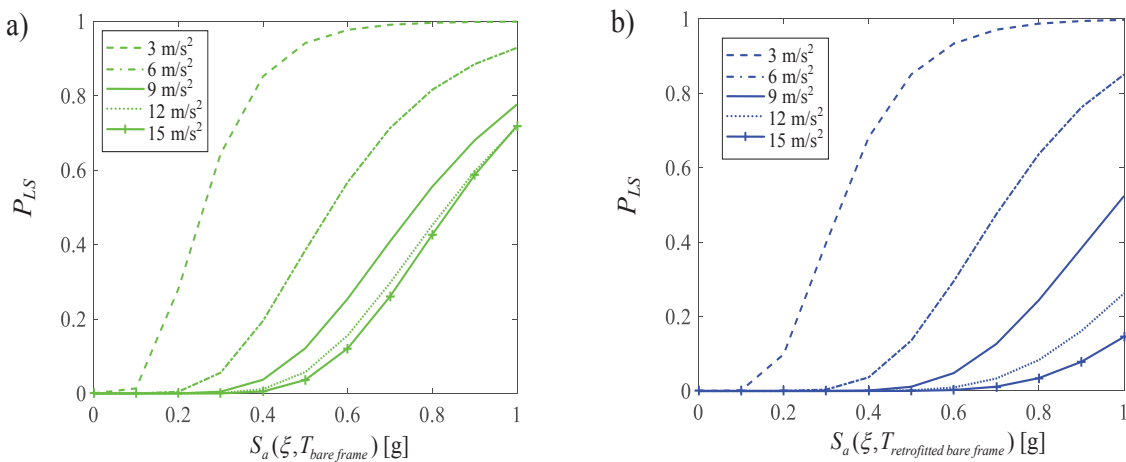

Figure 11. Conditional probability of exceedance vs. IM for the ACCs: a) Bare frame; b) Bare frame with BRBs.

It is noteworthy that the curves plotted in Figure 10-Figure 11 have been derived by considering different  $IM$ s for each of the models analysed. Thus, they could not be directly compared to each other. While in Freddi et al. [7] the concept of safety margin is used to compare fragility curves developed for a RC frame before and after the retrofit with BRBs, in this study seismic demand hazard curves, that are not conditional to the  $IM$ , are employed.

## 5 SEISMIC DEMAND HAZARD CURVES

Figure 12 shows the seismic hazard curves, expressing the mean annual rate (MAF) of exceedance  $\lambda$  of the various  $IM$ s considered in this study. These curves, plotted in semi-logarithmic scale, have been derived for the site in L'Aquila, where the structure is located, by following the procedure described in [34]. It can be observed that for the same level of the MAF of exceedance, the spectral acceleration is higher for the retrofitted frame than for the unretrofitted frame.

Figure 12. Seismic hazard curves for the unretrofitted frame and the frame retrofitted with BRBs obtained by neglecting the infill wall contribution.

The seismic demand hazard curves for the various systems and EDPs of interest are obtained by convolution of the conditional probability of exceedance (Figure 10 to Figure 11) with the relevant seismic hazard curve (Figure 12). The demand hazard curve for the generic EDP can be estimated as follows:

$$\lambda_{EDP}(edp) = \int_0^{\infty} G_{EDP|IM}(edp|im) \left| \frac{d\lambda_{IM}(im)}{d(im)} \right| d(im) \quad (4)$$

where  $d(\cdot)$  denotes the differential operator.

Figure 13 shows the demand hazard curves of the various EDPs of interest obtained for the structural models considered.

With regard to the  $IDR$ , it can be observed that the BRBs are effective to reduce the seismic demand to more acceptable values. In particular, the MAF of exceedance of the 0.5% threshold, commonly associated to onset of nonlinear behaviour of the frame, reduces from 0.0164 1/year to 0.0249 1/year, whereas the MAF of exceedance of the 2% threshold, associated to significant damage to the frame, reduces from 0.0037 1/year to 0.0001 1/year. Thus, the performance improvement is higher for high drift levels. It is also interesting to observe that the MAF of exceedance of the 1.5% limit, which is considered for the design of the BRBs, is equal to  $6 \cdot 10^{-4}$  1/year for the case of the retrofitted frame. This value is lower than the MAF

of exceedance of the design seismic input, which is  $2.1 \cdot 10^{-3}$  1/year. The discrepancy may be due to the simplifying assumptions of the design procedure, particularly the fact that the isotropic hardening behavior of the BRBs is neglected when evaluating the pushover curve of the retrofitted frame. Nevertheless, the MAF of exceedance is higher than the reference MAF of collapse that is targeted by the risk-based design approaches in the US [55]. In Europe, lower values of the MAF of collapse are sought for new structures, (about  $10^{-5}$ - $10^{-6}$  1/year [51], [55]).

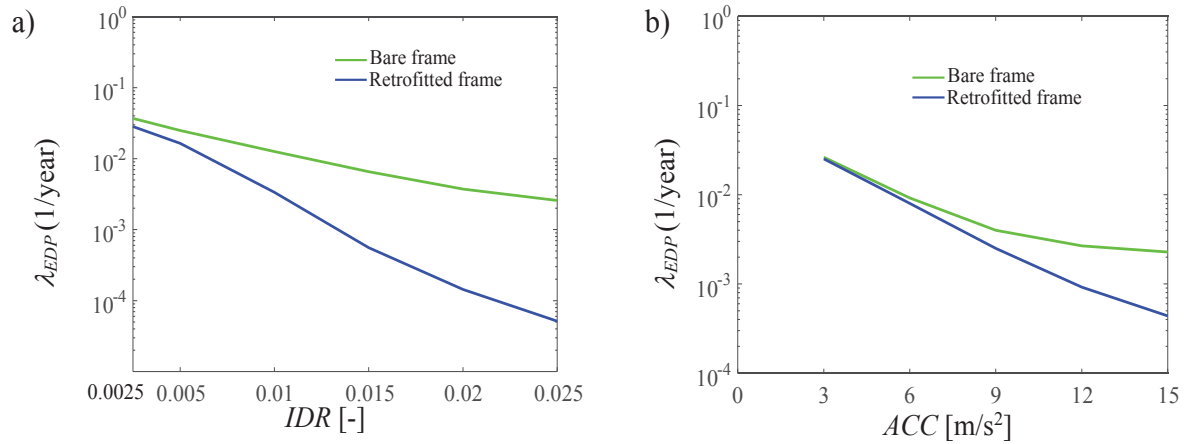

Figure 13. Demand hazard curves of the EDPs for the different structural models considered.

In Figure 13b, it is interesting to observe that the curve of the MAF of exceedance of the absolute accelerations is very similar for all the models for low acceleration values, below  $9 m/s^2$ . This is because adding the BRBs and the infills to the frame results both in a decrease of period, which would increase the acceleration demand, but also in an increase of energy dissipation, which on the other hand reduces the acceleration demand. Thus, this type of retrofit is not very effective in improving the performance of acceleration-sensitive non-structural components. Some improvements in terms of acceleration demand reduction can be observed for acceleration value higher than  $9 m/s^2$ . More details may be found in [56].

## 6 CONCLUSIONS

In this work, a performance-based approach is employed to evaluate the efficiency of the retrofitting of an existing RC building with buckling restrained braces (BRBs). In particular, an existing reinforced concrete building located in L'Aquila is used as case study. An advanced non-linear three-dimensional model of the existing RC building is defined in OpenSees, and a widely employed procedure based on pushover analyses is used to design the braces. Specifically, the bracing system is designed to obtain a retrofitted bare structure that is able to withstand the seismic demand associated to the life safety limit state design spectrum (return period of 475 years) experiencing a maximum absolute interstorey drift index of 1.5%. Successively, the seismic performance of the retrofitted bare building is evaluated by performing both non-linear static analyses and incremental dynamic analyses under a set of real ground motion records scaled to increasing seismic intensity levels. Seismic demand hazard curves are estimated for the interstorey drifts and other engineering demand parameters. The spectral acceleration at the fundamental period of the bare or infilled structure for a damping factor of 5% is used as intensity measure.

Based on the study results, the following conclusions can be drawn:

- Adding a relatively light BRB brace system to the existing frame results in notable performance improvements. In fact the use of the BRBs provides not only an increased ductility

capacity to the system, but also a reduction of the softening behavior following the attainment of the peak resistance, as shown by the capacity curves of the analysed models. The benefit in terms drift reduction due to the use of BRBs are also evident by observing the demand hazard curves for the IDRs. The MAF of exceedance of the 1.5% limit, which is considered for the design of the BRBs, is equal to  $6 \cdot 10^{-4}$  1/year for the case of the retrofitted frame with no infills, and it is about 1/10 of the corresponding MAF level for the case of the bare frame with no BRBs.

- The retrofit with BRBs does not reduce significantly the risk of exceeding absolute acceleration demands less than  $9 \text{ m/s}^2$ , but it more effective for higher acceleration levels. Thus, alternative retrofit measures may have to be employed if the seismic performance of acceleration-sensitive non-structural components has to be minimized.

### Abstract

*Seismic isolation bearings are one of the most widely used seismic protection systems for bridges. Taking advantage of improved energy dissipation and flexibility, Lead Rubber Bearings (LRB) have emerged as a popular solution for seismic protection of bridges. Over the last few decades, LRBs have been studied significantly both experimentally and numerically, resulting in different numerical modeling approaches of LRB. Since the seismic response of a base-isolated bridge largely depends on the modeling technique adopted for the bearing element, it is essential to identify an appropriate modeling scheme for LRBs. The objective of this study is to investigate the seismic response sensitivity of an isolated bridge when different LRB modeling techniques are adopted. In this study, a three-span curved steel girder bridge isolated with LRB is considered as the reference bridge that was tested in a shake table at the University of Nevada, Reno. The validated numerical model of the reference bridge is first developed using OpenSees. Three different LRB modeling techniques available in OpenSees are used to model the isolation bearings. Using the ElastomericX, LeadRubberX, and KikuchiAikenLRB modeling techniques, the seismic response of the bridge is compared against the experimental results. The performance of the isolated bridge is evaluated in terms of isolator force-deformation relationship and fragility curves. The analysis results show that LRB modeling approach has a noteworthy impact on the seismic response of base-isolated bridge and requires careful selection of modeling parameters.*

## 1 INTRODUCTION

Bridges are one of the vital infrastructures of any country's transportation network. Bridge damage due to a strong earthquake leads to the cessation of the function of these vital infrastructures at critical times, which are needed to provide emergency services or help evacuating a damaged area. The use of seismic isolators is one of the effective methods to improve the seismic performance of bridges. With seismic isolators, ductility increases, and forces applied to the bridge structure due to earthquakes decrease. The behavior and performance of seismic isolation systems are highly nonlinear and more complex than other structural elements (such as girders, cap beams, columns) and can be affected by several factors.

Behavioral characteristics of nonlinear seismic isolators are a function of the dynamic responses of seismic isolators during an earthquake, and this poses severe challenges for modeling the response of these seismic isolators. To overcome these challenges, several main aspects of isolation bearing modeling, are: (a) bidirectional motion coupling in the horizontal plane, (b) the relationship of vertical and horizontal motion of the seismic isolator, (c) cavitation behavior and post-cavity seismic isolator in tension, (d) decrease in tensile cyclic loading resistance during cavitation behavior, (e) changes in critical buckling load capacity due to lateral displacement [1].

The flexibility of seismic isolators increases the fundamental period of base-isolated bridges and reduces the seismic forces applied to them. Although this reduction may be associated with large horizontal displacements of the seismic isolators, lateral flexibility plus horizontal displacements result in a significant reduction in the critical buckling load capacity of the seismic isolator [2-5].

An experimental study by Buckle et al. [6] on a set of seismic isolators showed that the critical loading capacity decreases with an increasing horizontal displacement or shear strain, and the horizontal stiffness decreases with increasing axial load and horizontal displacement [2]. Recent studies and experience of past earthquakes have shown that the impact of considering the vertical component of ground motions is significant for the analysis and design of structures.

Shekar et al. [7] investigated the effect of dampers and design standards on the response of highway bridges. They developed a three-dimensional model for this purpose. A significant vulnerability of the non-seismic bridge designed with a bearing could be observed because of the bridge pier's non-ductile failure. With the modern seismic design, the vulnerability of the bridge was significantly reduced.

The objective of this study is to investigate the seismic response sensitivity of an isolated bridge when different LRB modeling techniques are adopted. In this study, a three-span curved steel girder bridge isolated with LRB is considered as the reference bridge that was tested in a shake table at the University of Nevada, Reno [8]. The distinguishing feature of this study is that conventional simplifications are not used in seismic isolator modeling techniques, and instead, the main aspects of modeling and the factors affecting the behavior of isolators are fully included in the modeling. For this purpose, Lead Rubber Bearing (LRB) is studied using different modeling techniques available in OpenSees, and by performing Incremental Dynamic Analysis (IDA) and fragility analysis, different bridge responses under near-fault ground motions are studied.

## 2 MODEL OF BRIDGE

### 2.1 Description

The bridge considered in this study was designed and experimentally tested at the University of Nevada, Reno [8]. The bridge is a three-span composite steel I-girder bridge. Fig.1 indicates the plan of the bridge model and shows the location of abutments and piers. The design and geometric details of the scaled bridge can be found in [8]. This bridge superstructure has three composite steel I-girders with an 83mm concrete deck. The lengths of the spans are 12.8, 18.6, and 12.8 m, respectively (total length 44.2 meters), and the centerline radius is 24.4 m. The width of the deck is 3.66 m and the distance between the girders is 1.37 m. The height of the columns and their diameters are 2.44 and 0.61 m, respectively.

Fig.2 shows the detailed numerical model of the bridge used in this study. The piers are mono-column with 1% longitudinal and transverse steel rebar ratios. The concrete compressive strength is 44 MPa and the steel reinforcement is A706 grade with a yield strength of 490 MPa. The total bridge model weight is 1486 kN that is spread along with the longitudinal nodes of the deck.

In the numerical simulation with OpenSees, the confined and unconfined concrete behavior is considered and calculated according to the Chang and Manders [28] model (Concrete07). The reinforcing steel properties are simulated using steel02 model. The superstructure elements are assumed as elastic element and the piers and LRB are considered as nonlinear elements. The effect of soil-structure interaction is ignored in this study.

### 2.2 Lead rubber bearing systems

Three modeling techniques are used for modeling LRB as a seismic base isolation system. The LRB characteristics such as, shear modulus, modulus of elasticity, and characteristic strength are 0.41 MPa, 1.24 MPa, and 6.27 (Abutment), 9.03 (Pier) kN, respectively. More details about designing the LRB can be found in [8]. Three techniques are used for modeling LRB in Opensees: (a) KikuchiAikenLRB material with the zero-length element, (b) ElastomericX element, and (c) LeadRubberX element. The fundamental period of the base-isolated bridge with three LRB modeling techniques is found to be 0.66, 0.68, and 0.68 sec, respectively.

Figure 1: Bridge Plan.

Figure 2: Numerical model of the bridge details.

### 3 MODEL VERIFICATION

The 2/5<sup>th</sup> scale bridge model was tested in shake table at the University of Nevada, Reno under the Sylmar station motion from the 1940 Imperial Valley earthquake as the Design Earthquake (DE). The tests were conducted at increments of 10% to 300% of the DE. To validate the numerical modeling approach adopted in this study, the test results obtained from the 100% DE is considered in this study. The hysteretic response of the LRB obtained from the shake table results are verified with the KikuchiAikenLRB, ElastomericX, and LeadRubberX modeling techniques. Fig.3 shows the hysteresis curves of the LRB at the pier location. According to this figure, the shape of the hysteresis curves is similar to the experimental hysteresis curve. In Table 1, the experimental responses in terms of the maximum shear force, displacement along the x-direction, both in positive and negative, and the energy dissipation are compared with the three mentioned techniques. For maximum shear force, all three models over predicted the force in the positive direction while under predicted in the negative direction. Similar observation can be made from the comparison of maximum bearing deformation. In terms of energy dissipation, the difference between the experimental and numerical results using KikuchiAikenLRB, ElastomericX, and LeadRubberX modeling techniques are 13%, 14%, and 9%, respectively.

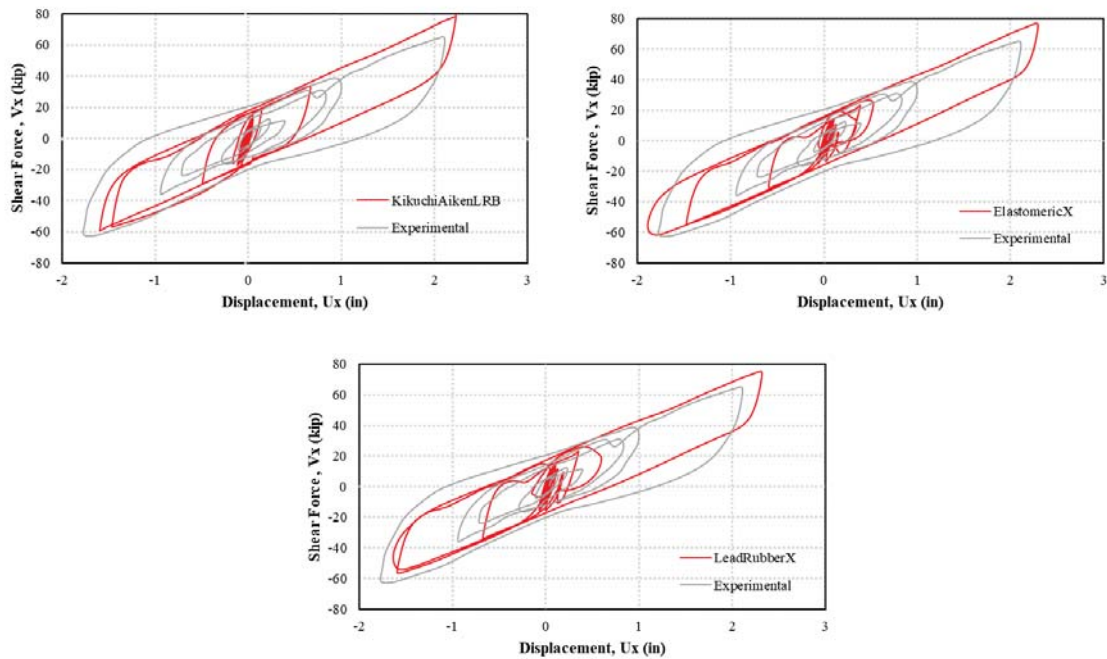

Figure 3: Hysteresis curve verification for LRB modeling techniques (a) KikuchiAikenLRB, (b) ElastomericX, and (c) LeadRubberX with Experimental result.

Parameters		Experimental	KikuchiAikenLRB	ElastomericX	LeadRubberX
Max. Shear force (kip)	+	64.89	78.80	76.86	75.24
	-	-62.67	-59.33	-61.75	-56.41
Max. Displacement (in)	+	2.10	2.23	2.29	2.32
	-	-1.78	-1.59	-1.89	-1.63

#### 4 GROUND MOTION SELECTION

After validating the numerical models, the sensitivity of the three modeling techniques is compared by conducting seismic fragility analysis of the isolated bridges. To develop fragility curves, appropriate ground motions according to FEMA P695 [29] are selected. Table 2 shows the characteristics of the selected 14 non pulse near-field ground motions for increment dynamic analysis (IDA). The ground motions are extracted from the Pacific Earthquake Engineering Research (PEER) earthquake database [9]. The recorded primary orientations (provided by PEER (NGA)) of selected ground motions are rotated to strike-parallel and strike-normal orientations. Individual response spectrum variation of selected records and mean and mean  $\pm$  standard deviation are illustrated in Figure 4.

ID No.	Earthquake			Recording Station		R <sub>rup</sub> (km)

## 5 ENGINEERING DEMAND PARAMETES (EDPs)

Bridge piers and base-isolation systems of the bridge typically govern the response of the bridge system over other elements. Diverse sorts of EDPs such as pier displacement, bridge pier ductility, isolation bearing displacement, bearing shear strain (%), etc., have been used by different researchers to quantify the damage in bridge pier and isolation bearing. Shear strain (%) or bearing displacement is usually used to define the damage states [10, 11] for the base-isolation system. In this research, damage states are defined in terms of base-isolation system shear strain (%) and bridge pier displacement ductility ( $\mu_d$ ). The experimental observations are considered to determine the damage states for the base-isolators resulting in pounding and unseating. Lead rubber bearing can take shear strain up to 400% before failure. Total deformation of bridge deck-girders and unseating issues in the whole bridge system are raised from such high strain. So this value is limited to 250% [12]. Limiting values for different damage

states are taken from Hwang et al. [13] and Zhang and Huo [14]. Outline of distinctive damage states' physical appearance and criteria are displayed in Table 3.

Damage State	→	Slight	Moderate	Extensive	Collapse	Ref
Bridge components	Physical phenomenon →	Cracking and spalling	Moderate cracking and spalling	Degradation without collapse	Failure leading to collapse	FEMA [15]
Bridge pier	Displacement ductility $\mu_d$	$\mu_d > 1.0$	$\mu_d > 1.2$	$\mu_d > 1.76$	$\mu_d > 4.76$	Hwang et al [13]
LRB	Shear strain $\gamma$ (%)	$\gamma > 100$	$\gamma > 150$	$\gamma > 200$	$\gamma > 250$	Zhang and Huo [14]

Table 3: Damage states of bridge components.

## 6 SEISMIC FRAGILITY ANALYSIS

The fragility curve expresses the probability of damage corresponding to a given damage state at several levels of seismic events. In fact, the fragility curve describes the relation between the intensity measure and the level of possible seismic damage. In order to accurately develop fragility curves, it is important to choose an appropriate earthquake intensity measure for structure under study. Intensity measures that indicate the severity of the earthquake as appropriate for fragility analysis include  $S_a$ , PGA, PGV, and PGD. Fragility curves can be obtained from logical regression analysis of real or simulated damage information or numerical solution methods.

Fragility curves distribute the failure between slight, moderate, extensive, and collapse states according to HAZUS-MH [15]. These curves are plotted separately for each damage state for a set of ground motions and are used as input to the structural damage calculation.

Researchers have previously used various methods to obtain fragility curves [16]. Billah and Alam [16] have surveyed diverse methods and proposed a technique to obtaining a hybrid fragility curve. The research examined the preferences, shortcomings, and imperatives of all the strategies in assessing seismic vulnerability of bridges. The fragility function is a probabilistic method that portrays the probability of damaging a structure beyond a specific damage level for a certain ground motion intensity [17]. The fragility of a structure, is expressed as the conditional probability of a damage state (DS) occurring given a specific intensity measure (IM), which can be expressed mathematically as [18]:

$$Fragility_{DS}(y) = P[DM \geq DS | IM = y] \quad (1)$$

The relationship of the engineering demand parameter (EDP) and the IM is set up by a probabilistic seismic demand model (PSDM) in this research. By utilizing the incremental dynamic analysis (IDA) on the bridge system, the PSDM is formed. There are two methods to create the PSDM: the scaling approach [10, 14] and the cloud approach [19, 20, 21, 22]. The cloud method is utilized in assessing the seismic fragility function of the bridge piers and lead rubber bearing systems in this study.

The shear strain (%) of the LRB and pier displacement ductility are selected as the EDPs, and the spectral acceleration at the fundamental period of the bridge ( $S_a$ , T1) of each ground motion is taken as the IM. Regression analysis is performed to obtain the mean and standard deviation of each damage condition by assuming the power-law function [23] in the cloud method. The logarithmic relationship between IM and median EDP is expressed as follows.

$$EDP = a(IM)^b \text{ or, } \ln(EDP) = \ln(a) + b \ln(IM) \quad (2)$$

In this correlation,  $a$  and  $b$  are coefficients that can be estimated from a regression. The lognormal distribution is recommended for the EDPs by Gradoni et al. [24]. In order to obtain adequate data for the cloud approach, IDA is carried out rather than the nonlinear time history analysis. The ground motions are scaled from a very low IM to a high IM for the IDA. The time history analysis and scaling are repeated until dynamic instability in the shape of large drifts occurs, demonstrating structural collapse. This reduced the computational time and provided adequate damage data for generating fragility curves. Each intensity level of a specific ground motion can be considered as a one-time history analysis. Hence, it was possible to generate adequate damage data corresponding to a diverse ground motion intensity levels. The logarithmic standard deviation (dispersion) of the demand parameters,  $\beta_{EDP|IM}$  conditioned upon the IM is estimated using the following equation [25].

$$\beta_{EDP|IM} = \sqrt{\frac{\sum_{i=1}^N (\ln(EDP) - \ln(aIM^b))^2}{N-2}} \quad (3)$$

In this equation,  $N$  is the number of simulation cases.

Fragility curves are created utilizing the following equation from Padgett [26].

$$P[DS|IM] = \Phi \left[ \frac{\ln(IM) - \ln(IM_n)}{\beta_{comp}} \right] \quad (4)$$

In this equation,  $\Phi [ ]$  is the standard normal cumulative distribution function and

$$\ln(IM_n) = \frac{\ln(S_c) - \ln(a)}{b} \quad (5)$$

$IM_n$  is characterized as the median value of the intensity measure for the chosen damage states. The following equation presents the dispersion [26].

$$\beta_{comp} = \frac{\sqrt{\beta_{EDP|IM}^2 + \beta_c^2}}{b} \quad (6)$$

In this equation,  $S_c$  and  $\beta_c$  are the median and dispersion values for a specific damage state of the bridge components (bridge pier and isolation bearing), respectively. The coefficient of variation (COV) is related to each damage state for related uncertainties. COV is assumed to be 0.25 for slight and moderate damage states and 0.5 for the extensive and collapse damage states [18]. The following equation is used to calculate the dispersion value [27].

$$\beta_c = \sqrt{\ln(1 + COV^2)} \quad (7)$$

The total bridge system fragility function is more conceivable than the individual component fragility function [14, 19, 21, 22]. The global damage likelihood can be simply assessed utilizing the series system and first-order reliability theory. Moreover, the upper and lower bound of failure likelihood of the bridge can be determined utilizing Eq. (8). Both bounds present a conservative and un-conservative estimation of damage likelihoods, respectively.

$$\max_{i=1}^n [P(F_i)] \leq P(F_{system}) \leq 1 - \prod_{i=1}^n [1 - P(F_i)] \quad (8)$$

In this equation,  $P(F_i)$  represents the probability of exceeding the prescribed bound of the component's actual damage state. Moreover,  $P(F_{\text{system}})$  is for the whole bridge system.

## 7 RESULTS

Fragility functions are developed for the based-isolated curved bridge considering the fragilities of the pier and LRB for various modeling techniques. The fragility functions, assuming a lognormal distribution with respect to the median of seismic intensity ( $S_a$ ,  $T_1$ ), are generated using Eq. (4), and calibrated with the damage states as shown in Table 3. To evaluate the effect of LRB modeling techniques on the relative fragility of each component, fragility curves are developed for the piers and isolation bearings at abutments and piers. However, the fragilities of the pier and abutment bearings are not provided here due to space limitations. Fig. 5 compares the fragility curves for the LRB at four damage states. Fig. 5 shows that when LRB is modeled using KikuchiAikenLRB technique, independent of the considered damage level, LRB is less vulnerable during a seismic event. As the damage level changes from slight to collapse, the contrast between the relative vulnerability of KikuchiAikenLRB and other techniques increase and become more visible. This interpretation is also accurate for the LeadRubberX and ElastomericX techniques, but its value is less obvious.

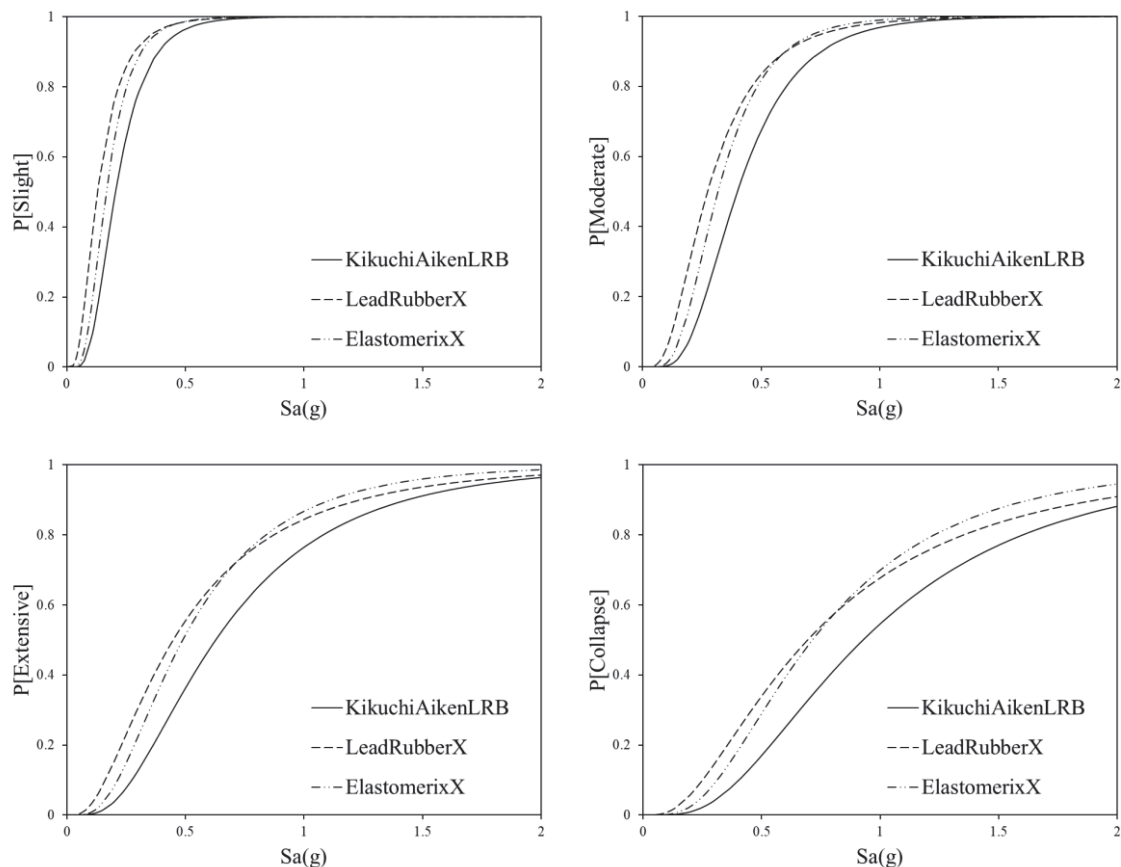

Figure 5: Comparison of fragility curves of LRB.

As the collapse of bridge components (column and/or bearing) will lead to the collapse of the bridge, the fragility curves of each component should be combined to get a system fragility curve. After obtaining the bridge component fragility curves, the bridge system fragility

curves are determined according to Eq. (8). Fig. 6 shows the system fragility curves of the bridge with various modeling techniques. The same observation can be seen as a bearing isolation system for the bridge system, as utilizing KikuchiAikenLRB can lead to a reduced damage compared to the other techniques. The bridge fragility curves of ElastomericX and LeadRubberX techniques are very similar. The bridge system fragility demonstrates that system fragility is generally influenced at the extensive and collapse damage level due to the using KikuchiAikenLRB techniques. It is also observed that the ElastomericX and LeadRubberX have almost identical fragility curves.

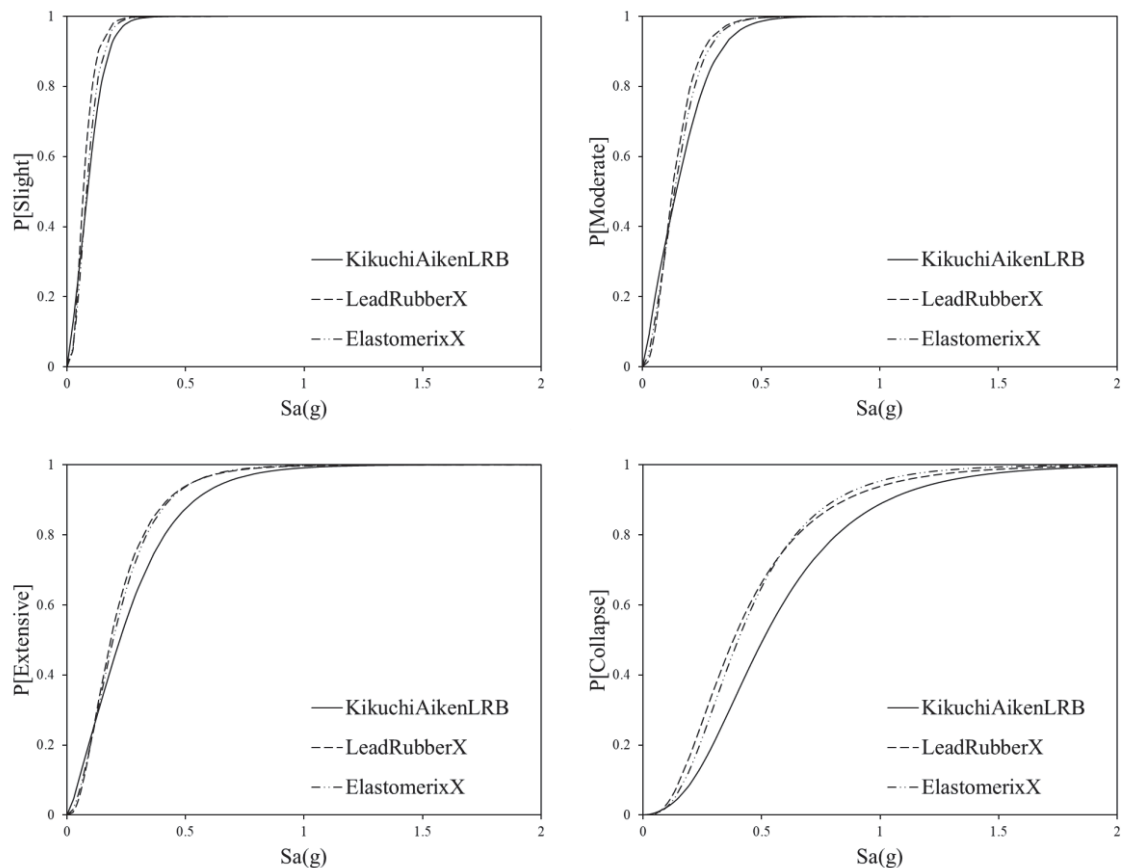

Figure 6: Comparison of fragility curves of Bridge System.

## 8 CONCLUSIONS

In this paper, various bearing isolation modeling techniques are assessed in terms of pier displacement and LRB deformation. Increment dynamic analysis is implemented to derive the appropriate data for fragility analysis. Then, seismic fragility curves are obtained for each bridge component as well as the bridge system. According to the results of the numerical analysis, the following conclusions are drawn:

- KikuchiAikenLRB is susceptible to lower shear force as compared to ElastomericX and LeadRubberX significantly.
- The influence of modeling techniques on the fragility of LRB shows increased susceptibility of exceeding different damage states in ElastomericX and LeadRubberX techniques compared to the KikuchiAikenLRB technique.

- Extensive and collapse damage states of the bridge system fragility considering the KikuchiAikenLRB technique is mostly affected than the other two techniques.
- The likelihood of an isolated bridge exceeding collapse damage level is highly dependent on the adopted modeling techniques. The higher probability of the bridge experiencing collapse is mainly attributable to the fragility of the bearings arising from the LeadRubberX and ElastomericX LRB modeling techniques.

### Abstract

*Fluid viscous dampers have proven to be a very efficient solution for reducing the seismic demand on structural and non-structural components, for both new and existing structures. Nowadays, the topics, which need to be further investigated, deal with the reliability and robustness of such kind of energy dissipating devices. Damper failures are generally brittle mechanisms, which can compromise the capacity of the structure to withstand the seismic action, leading to a lack of robustness of the overall system.*

*In this study, an advanced model, which is able to describe the fluid viscous damper brittle failure, has been developed in OpenSees and is discussed. The failure of a damper is related to the exceedance of its strength capacity and can be attained because of the forces arising related to the end-stroke impact or can be due to excessive piston velocity (over-velocity). The effect of damper failure on the seismic performance of the structural system is investigated by performing multi-stripe analyses and monitoring different global and local demand parameters. The proposed model for the damper is applied to a benchmark structure, consisting on a 3-storey steel moment resisting frame.*

## 1 INTRODUCTION

Fluid viscous dampers (FVDs) are devices widely used for seismic passive protection of both new and existing structures. They are widely employed for reducing displacements and interstorey drift demands in newly-designed structures as well as in existing ones by using both external and internal configurations [1]-[8].

Several approaches are to date available for designing both size and location of viscous dampers within a building frame based on direct procedures [1][9][10][11][12] or optimization methods [13][14]. These design approaches generally allow to control the seismic performance of buildings under the design seismic intensity level. However, the reliability under extreme, low-probability earthquake events may be characterized by low robustness and inadequate safety levels because dampers usually exhibit a brittle collapse behaviour and their failure may trigger the collapse of the whole system. As a consequence, more accurate studies simulating the effect of the device failure should be carried out to provide a better evaluation of the structural reliability under strong earthquakes.

In order to shed light on this aspect, the present paper introduces a model able at describing the brittle failure of FVD devices and its influence on the structural reliability. The collapse is due to the attainment of the force capacity of the damper, related to the over-velocity or to the achievement of the end-stroke. In particular, it is assumed that a brittle failure occurs in the device once the maximum force is attained, consistently with the viscous damper numerical model proposed in [15]. This way, the proposed model can be suitable to describe the consequences of the failure of the devices on the seismic performance of structural systems and also to evaluating the probability of collapse of structures equipped with dampers, through risk analyses performed by using probabilistic approaches [16]-[24].

Recent probabilistic analyses, indeed, have already investigated some specific issues, such as the effect of ground motion variability on the response of systems equipped with either linear and nonlinear viscous dampers [19][20][21]; the influence of the degree of nonlinearity of the dampers [20][22], and the effect of the damper parameters variability [22][23][24] stemming from the device manufacturing process, as acknowledged by the main international Standards for seismic structural design [25][26][27][28]. However, in these studies the device failure was not explicitly taken into account.

The proposed model is firstly described in the following section and then it is applied to a three-storey steel building case study, already considered as benchmark structure in previous studies (SAC Phase II Steel Project, [29]). For consistency with the adopted benchmark case study, the seismic hazard is also assumed equal to the one of [29]. The dissipative system is dimensioned to provide an added damping equal to 30%, using both linear and nonlinear devices, by varying their degree of nonlinearity among two boundary values. The capacity of the dampers (stroke and strength) is evaluated at the design condition, corresponding to a seismic action with Mean Annual Frequency (MAF) of exceeding equal to  $2 \cdot 10^{-3}$ .

Some preliminary results under increasing harmonic load histories are reported to illustrate the model capabilities and the sequence of failures triggered by the damper failure. Subsequently, few selected results from Multi Stripe Analysis (MSA) are also presented to illustrate overall the problem of damper failure and related effects on the structural performance of the case study. Finally, a preliminary evaluation of the overall probabilistic response is provided. Results obtained by considering the failure of the dampers are compared with those achieved with two limit cases, that is the condition of no failure, where no damper's failure is permitted and the bare frame, which represents the building without FVDs.

Further details regarding fragility curves and demand hazard curves, where the structural performance is analysed considering MAF of exceeding up to  $10^{-5}$  1/yr, can be found in [30].

## 2 FLUID VISCOUS DAMPERS MODELLING

The constitutive law of a fluid viscous damper (FVD) can be described through the following relationship [15][31]:

$$F_d(v) = c|v|^\alpha \text{sgn}(v) \quad (1)$$

where  $v$  is the relative velocity between the device ends,  $F_d$  is the damper resisting force,  $|v|$  is the absolute value of  $v$ ,  $\text{sgn}$  is the sign operator,  $c$  and  $\alpha$  are two constitutive parameters: the former is an amplification factor, while the latter describes the damper nonlinear behaviour.

It is worth noting that viscous dampers can be produced with  $\alpha$  values ranging from 0.1 and 2. Devices with  $\alpha > 1$  are not dissipative and are used as shock transmitters. Devices with  $0.1 \leq \alpha \leq 1.0$  are all potentially suitable for seismic energy dissipation, among these values, the range  $0.3 \leq \alpha \leq 1.0$  is the most widespread [32][33][34][35].

A fluid viscous damper generally consists of a steel cylinder filled of a silicone fluid, within which a steel piston with small orifices on its head can move. In case of seismic events, the fluid is forced to pass through the orifices, moving from one side to the opposite side of the cylinder, thus dissipating into heat the input mechanical energy. The higher is the velocity of the movement, the greater is the dissipated energy. The cylinder is equipped with spherical hinges at its ends to avoid device bending. FVDs are generally connected to the structure by a stiff connection, consisting in a driver brace, dimensioned using an over-strength factor with respect to the viscous device. The stiffness of the driver brace is an important feature, because it needs to be sufficiently high to allow the device to be effective in dissipating energy. Further details on the damper components and their behaviour can be found in [15].

The failure of a damper is related to the exceedance of its strength capacity and can be attained because of the forces related to the end-stroke impact or can be due to excessive piston velocity. According to the described behaviour, dampers are generally classified and tested with reference to two characteristic parameters: the maximum values of stroke  $\Delta_{d,max}$ , and the maximum transmissible force  $F_{d,max}$ .

The end-stroke can be attained both in tension (maximum elongation of the device) and in compression (maximum shortening of the device). During a seismic event with an intensity higher than the design level of the device, it may happen that the device exploits the entire available stroke, resulting in an impact. At the instant of the impact, the velocity becomes null and the force notably increases, however, the attainment of the impact does not strictly imply the damper failure because the impact force may be lower than the device strength.

The second mechanism refers to the attainment of the maximum viscous force due to an excessive value of the velocity of the piston (over-velocity with respect to the design value). This extreme value of the force can induce a leak of the fluid or can damage the damper components, resulting in the failure of the device. It is noteworthy that once the maximum capacity ( $F_{d,max}$ ) is attained, the resulting failure mechanisms is brittle, thus making the device ineffective, with no residual ability to sustain loads or dissipate energy.

The model, proposed hereinafter, aims to describe the two aforesaid mechanisms using the damper model, depicted in Figure 1. It is composed of three elements: a dashpot, describing the dissipative behaviour; a hook and gap element, set in parallel to the dissipative device, which simulate the impact due to either excessive shortening ( $-\Delta_{d,max}$ ) or elongation ( $+\Delta_{d,max}$ ); and a third element, set in series with the others, simulating the failure due to the attainment of the force capacity. In this paper, the strength capacity is assumed to be the same in traction and in compression and the failure occurs when the modulus of damper force attains the limit value  $F_{d,max}$ .

The damper model discussed above is implemented in OpenSees [36] using two-node link elements simulating each of the three components, while various material properties are used to describe the different behaviours. A “Viscous material” is used for the dissipative element, by assigning the values of the constitutive parameters  $c$  and  $\alpha$ . An “ElasticMultilinear material” depicts the force-displacement relationship related to impacts occurring both for elongation and shortening. Finally, a “MinMax material” is used to simulate the brittle failure, assigning the value of the strength capacity  $F_{d,max}$ . The stiffness of the “MinMax material” can be used to model the overall deformability of damper, connections, and brace. However, once the strength capacity is reached, the element fails and does not provide any more contribution in terms of reaction force.

### 3 CASE STUDY

In this section, the case study, dealing with a steel moment-resisting frame structure representative of low-rise buildings is introduced together with the considered seismic scenario. The frame is equipped with FVDs with both linear and non-linear behaviour that is values of the damper exponent  $\alpha$  corresponding to 1.0 and 0.3.

#### 3.1 Benchmark structure and hazard scenario

The three-storey building selected as case study is a steel moment resisting frame designed within the SAC-FEMA project with reference to gravity, wind and seismic load in compliance to the code requirement. It has been also widely used as benchmark structure in several studies concerning structural response control (e.g., [2][29][20]). The structural system of the building consists of perimeter moment-resisting frames and internal gravity frames with shear connections. The finite element model of the building (Figure 2) is a two-dimensional model representative of the weak and short direction of the building and has been developed in OpenSees following a non-linear fiber distributed approach, whose details can be found in [30].

Figure 2: Building model descriptions: locations of the dampers (in red) and cross-sections of the members.

For consistency with the adopted benchmark case study, the hazard model and the related IM hazard curves are taken from [29]; however, the curves have been slightly extrapolated to make sure that the system failure probabilities can be accurately estimated, by following the recommendation of [37] about the optimal IM curve truncation for an accurate risk estimation via MSA analysis. The spectral pseudo-acceleration  $S_a(T_1)$  of a linear elastic SDOF system with 2% damping ratio and fundamental vibration period equal to that of the structure  $T_1$  is considered as intensity measure (IM). MSA is performed at 20 IM levels, with a set of 30 ground motions per each intensity level taken from the 60 records used in the SAC project [2].

For what concerns the FVDs design, this is carried out by considering the set of 30 records corresponding to a MAF of exceedance  $\nu_{design} = \nu_{IM}(im_{design}) = 0.0021$  1/yr. Further details and features of these records can be found in [30].

### 3.2 Damping system

The design of the FVDs is carried out to enhance the performance of the building under a seismic scenario with a 10% probability of exceedance in 50 years (ULS scenario according to Eurocode 8). To this aim, a target value  $\xi_{add} = 30\%$  has been chosen for supplemental damping. In the present study, the damping coefficients of the linear devices have been distributed proportionally to the storey shear of the first mode of the bare frame.

Once determined the damping coefficients of the devices for the linear case, the viscous coefficients for the nonlinear FVDs corresponding to given value of the exponent  $\alpha$ , are evaluated following the approach outlined in [9][38][39] and based on the equivalence of the energies dissipated by the linear and nonlinear FVDs. It is noteworthy that the maximum interstorey drift along the building height without dampers, averaged over the 30 records considered, is equal to 3%, while with the addition of the dampers, it becomes 1.2%.

Table 1 and Table 2 report, respectively, the damping properties and the design parameters of the FVDs of the three elevations of the building for both the values of the constitutive parameter  $\alpha$ . Further details concerning the dissipative devices design can be found in [30].

$\alpha$	$c_1$	$c_2$	$c_3$
	$[kNs^\alpha/m^\alpha]$		
1	13,780	11,914	7428
0.3	4669	4037	2517

Table 1: Damping properties for different levels of damper nonlinearity.

$\alpha$	$\Delta_{d,1}$	$\Delta_{d,2}$	$\Delta_{d,3}$	$F_{d,1}$	$F_{d,2}$	$F_{d,3}$
	$[mm]$	$[mm]$	$[mm]$	$[kN]$	$[kN]$	$[kN]$
1.0	35.4	44.5	37.1	3109	3336	1956
0.3	29.6	39.7	35.7	3044	2796	1712

Table 2: FVD design parameter at the design condition.

### 3.3 Amplification factors for the FVD control parameters

Modern seismic codes prescribe that anti-seismic devices shall be dimensioned starting from the values of the control parameters evaluated for seismic design actions having an assigned probability of exceedance. Then, the capacities of the devices are assigned amplifying these

control parameters, which are stroke and force for the FVDs, by means of amplification factors, or reliability factors, in order to ensure a target level of safety.

The amplification factors proposed by Codes are two and aim to control the two failure mechanisms discussed above. The former, here denoted by  $\gamma_\Delta$ , amplifies the maximum stroke measured at design condition. The amplified stroke must not exceed the damper capacity  $\Delta_{d,max}$ . The latter, here denoted by  $\gamma_v$ , amplifies the maximum velocity measured at design condition. Damper force is obtained by Eqn. (1) and must not exceed the damper capacity  $F_{d,max}$ .

Per each value of the constitutive parameter  $\alpha$ , five combinations of amplification factors relevant to damper stroke and strength are considered, ranging from 1.0 up to 3.0, considering also, the prescriptions of European codes [26][27] and American Standards [28]. Moreover, for comparison purposes, two more limit cases are considered: “No Failure” that is the case where no dampers’ failures are permitted, and “Bare Model”, which represents the frame without FVDs. Further details concerning the combinations of amplification factors can be found in [30].

#### 4 SYSTEM RESPONSE UNDER AN INCREASING SINUSOIDAL INPUT

In this section, the results obtained for a sinusoidal ground motion of increasing intensity are presented. The FVDs response parameters at the design condition refer to linear devices ( $\alpha = 1$ ) without amplification factors, that is  $\gamma_v = \gamma_\Delta = 1.0$ .

The choice of an increasing harmonic input motion is motivated by the fact that it allows to easily identify the attainment of the damper strength capacity through one of the two mechanisms, impact and over-velocity and the related consequences on the frame undergoing a more general time-history input motion.

Figure 3 shows the sinusoidal input having a period of 0.9 seconds and an initial magnitude of  $1 \text{ m/s}^2$ . The amplitude of the motion is constant for five cycles, after that it is increased with a coefficient equal to 1.5 and remains again constant for five cycles. The magnification of the motion amplitude is repeated four times, resulting in a motion that has five different amplitudes, with a maximum equal to  $5 \text{ m/s}^2$ , and that lasts 22.5 seconds. At the end of the input, there are few seconds, which are useful to understand how the case study restores its rest condition.

Figure 3: Sinusoidal incremental dynamic input.

Figure 4 a) and b) illustrate the time-history of the damper forces  $F_{d,i}$  recorded along the height of the building. The black solid line refers to the device installed between the ground and the first floor, the red one refers to the intermediate device at the second storey, while the blue one represents the damper at the top storey. At the beginning of the third increment of the

sinusoidal input (between 14.4 and 14.5 seconds), graphs show some small ripples, which are more evident for the intermediate and top-storey devices (Figure 4 b), and they are caused by small impacts due to the end-stroke attainment. In this case, the impact occurs but it does not lead to the attainment of the damper strength capacity. At the time instant 14.6 s the damper placed at the first level reaches its force capacity due to over-velocity and its force drops to zero. Few instants later, also the other devices fail for over-velocity.

Figure 4: Time-history of the damper forces along the height of the building.

The effects of the damper failure can be deeper investigated through Figure 5 a) - c), where the stroke-force relationship ( $\Delta_{d,i}-F_{d,i}$ ) of each device is shown. In particular, by observing these stroke-force relationships it is evident that at the beginning of the third increment of the input motion, all the three dampers experience the end-stroke attainment without failure, with impacts that are more evident for the intermediate and top-storey devices. After these impacts, occurred without consequences, the FVDs restore their behaviour as pure dissipative devices. Few instants later, suddenly, the damper located at the ground floor fails due to over-velocity (Figure 5 a), triggering the sequence of damper failures at the upper elevations. The sequence is highlighted by a series of ripples in the stroke-force relationship of the intermediate (Figure 5 b) and especially top-storey device (Figure 5 c). The ripples begin when the first device fails and last until all the devices fail for over-velocity.

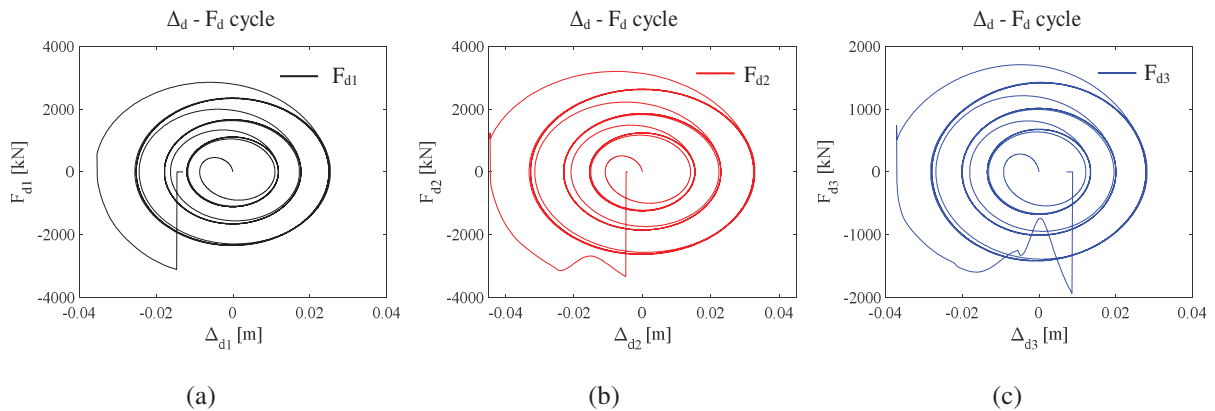

Figure 5: Stroke-force relationships of the devices.

Figure 6 a) - c) shows the time-histories of the parameters strictly related to the frame response, that is floor displacements  $u_i$ , floor relative velocities  $v_{r,i}$  and floor absolute accelerations  $A_i$ , highlighting the consequences of the damper failures on the frame itself. Generally, all the responses are significantly amplified by the impacts occurring in the dampers and by their failure. The absolute accelerations (Figure 6 c) are more affected than the displacements (Figure 6 a). It is worth to note that the peaks in terms of absolute accelerations, recorded between 14 and 15 seconds, are mainly related to the impacts experimented by the devices before their failure.

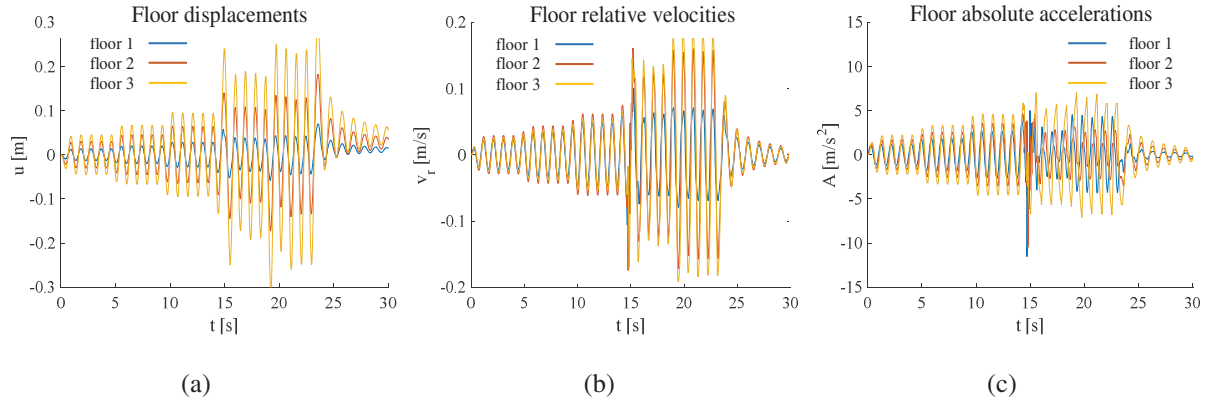

Figure 6: Time-histories of the response parameters of the frame.

## 5 SYSTEM SEISMIC RESPONSE

To shed further light on the consequences of FVDs failure, this subsection shows few selected information from MSA analyses to illustrate overall the problem of damper failure and related effects on the structural performance of the case study. The results refer to both low (*IM* level 5) and high (*IM* level 15) seismic intensities and for a single time-history (TH) analysis (TH 25).

Figure 7 a) and b) compares the time-histories of the interstorey-drift ratio (IDR) response of the bare model and of the system with linear and nonlinear dampers designed without amplification factors ( $\gamma_v = \gamma_\Delta = \gamma = 1.0$ ) at both the seismic intensity levels. The response in terms of IDR at floor 1 is only discussed, given the high similarity of the response at all floors.

Figure 7: Time histories of the IDR at *IM* level n. 5 (a) and (b) *IM* n. 15. Comparison between the bare model and the model with linear and nonlinear dampers (without amplification factors).

As already shown for the incremental harmonic input, it is confirmed that at lower seismic intensities FVDs are effective in damping the response, while the beneficial mitigation of the response provided by the dampers vanishes at higher *IMs*, due to their failure. At *IM* level 5, indeed, the response of the frame with FVDs is damped over the whole earthquake duration, since no device failure is observed at this intensity level. From the inset of Figure 7 (b), instead, it can be observed that dampers fail at around 2.5 seconds since the beginning of the time-history of *IM* level 15, therefore the IDR response is damped until that time instant, while later on the response tends towards the bare-frame response.

To deeply understand the FVDs behaviour along the height of the building, Figure 8 compares the time histories selected from the *IM* level 15 (higher intensity) of the force on dampers at all the three elevations of the building. Here dampers failure occurs quite simultaneously at 2.5 s, when the forces suddenly drop to zero and the dampers become ineffective.

Figure 8: Failure time-lag among dampers at different floors.

For sake of completeness, the dampers force-stroke cyclic responses corresponding to the cases plotted in Figure 7 are shown in Figure 9 (*IM* level 5) and Figure 10 (*IM* level 15). In each figure a comparison is made between the responses of the linear (red dashed line) and nonlinear dampers (blue dotted line) at the first (figure a) and third storey (figure b). It is worth to observe that at *IM* level 5 (Figure 9 a) and b) there is no evidence of impact and the failure is never attained, thus complete cycles can be observed.

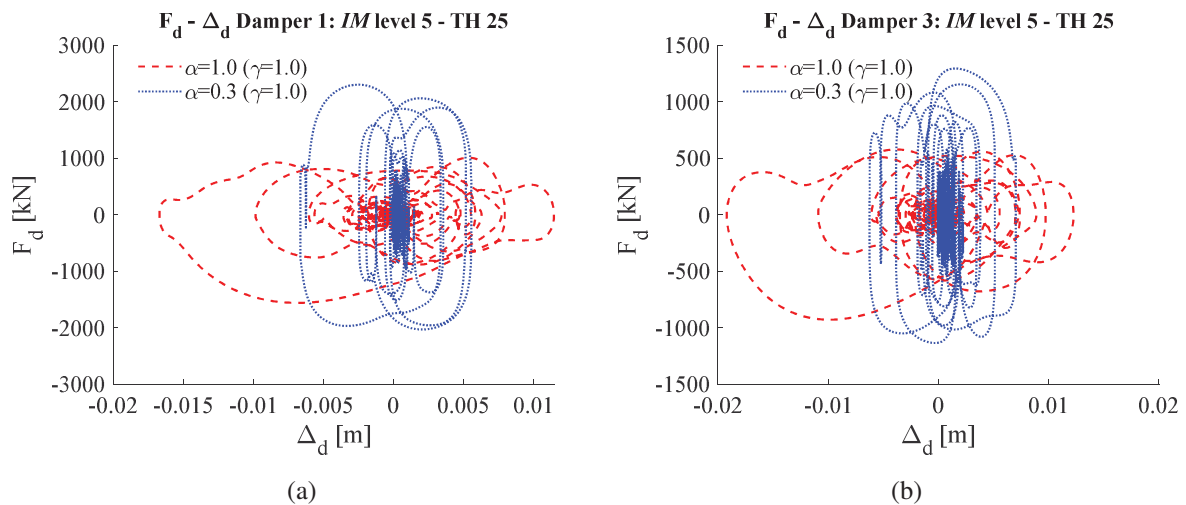

Figure 9: Damper response at *IM* levels 15. Comparison between linear and nonlinear dampers (without amplification factors) at (a) first and (b) third floor

In Figure 10 a) and b), instead, the attainment of the maximum force capacity (hence the failure), for both linear and nonlinear dampers, is due to over-velocity because the force suddenly becomes null and the hysteretic cycle is suddenly interrupted, without any impact.

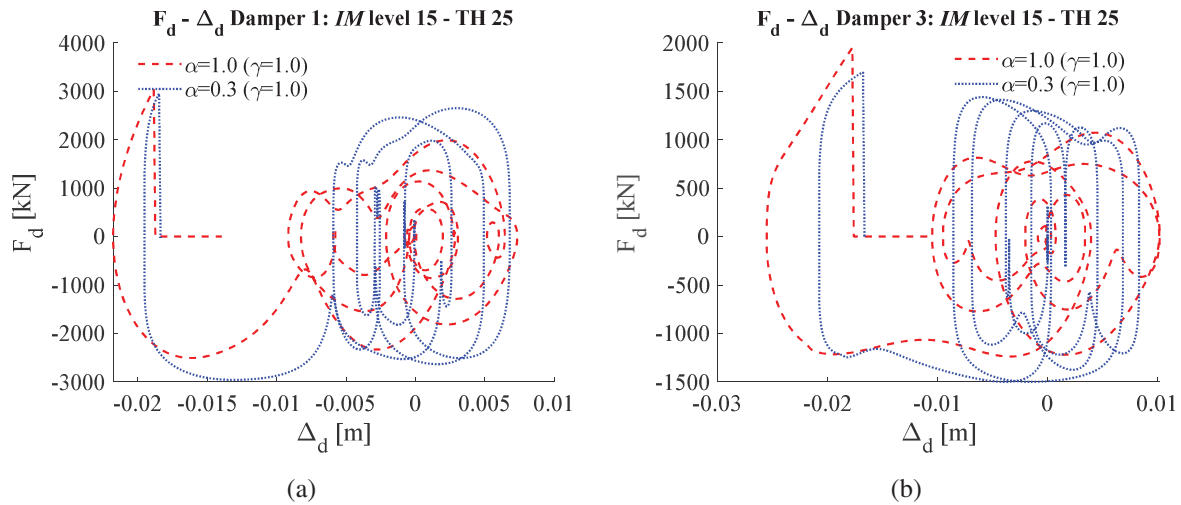

Figure 10: Damper response at *IM* levels 15. Comparison between linear and nonlinear dampers (without amplification factors) at (a) first and (b) third floor.

### 5.1 Preliminary evaluation of the overall probabilistic response

This section provides a preliminary evaluation of the overall probabilistic response of the analysed case study in terms of global engineering demand parameters (EDPs). First, the median response of the building at different *IM* levels is presented, then the demand hazard curves, with respect to the mean annual rate of exceedance,  $\nu_D$ , of the same EDPs are introduced. The monitored parameters are the maximum interstorey drift (IDR) and the maximum absolute acceleration (A) recorded among the various storeys.

The median response of the building at different seismic intensities for the case of linear dampers ( $\alpha = 1.0$ ) is compared in Figure 11. The comparison involves the following three cases: 1) bare model (black line); 2) building with dampers designed without amplification factors ( $\gamma_v = \gamma_\Delta = 1$ ) (blue line); 3) building with no dampers' failure permitted ( $\gamma_v = \gamma_\Delta = \infty$ ) (red line).

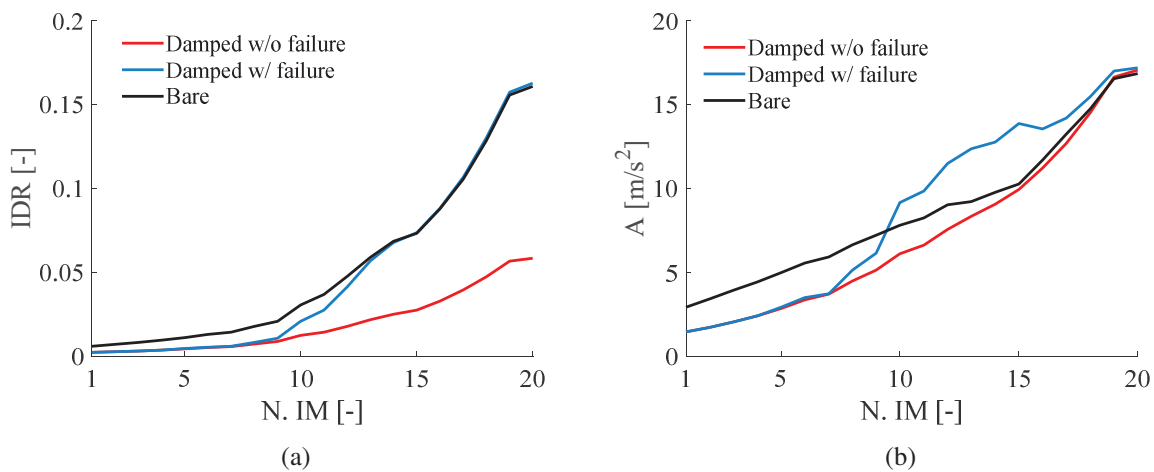

Figure 11: Building response at different *IM* levels for the case with linear dampers ( $\alpha=1.0$ ) in terms of (a) IDR and (b) A. Comparison between damped (with and without failure) and bare model.

Based on the results depicted in Figure 11 a) and b), it can be observed that the case of FVDs without failure notably reduces the response in terms of IDR up to the highest seismic intensities, while the beneficial effect in terms of acceleration mitigation is lower. On the other hand, in the case of FVDs that can fail, the IDR response of the damped systems tends to be almost that of the bare building once the devices are no longer effective (for  $IM$  levels higher than 10). The response in acceleration  $A$ , instead, shows peaks higher than the undamped frame system, due to the impacts induced by the devices end-stroke attainment.

Finally, Figure 12 a) and b) provides a first insight regarding the demand hazard curves of the maxima IDR and  $A$  among the storeys, with respect to the mean annual rate of exceedance  $\nu_D$ , for the linear dampers only ( $\alpha = 1.0$ ).

The demand hazard curves compare the results achieved when accounting for different values of the amplification factors, previously introduced in section 3.3. The analysed cases are: dampers without amplification factors ( $\gamma_v = \gamma_\Delta = 1.0$ ) (blue solid line) and dampers designed with different  $\gamma$  factors, that is  $\gamma_v = 1.5$  and  $\gamma_\Delta = 1.0$  (brown solid line);  $\gamma_v = \gamma_\Delta = 1.5$  (yellow solid line);  $\gamma_v = \gamma_\Delta = 2.0$  (violet solid line);  $\gamma_v = \gamma_\Delta = 3.0$  (green solid line). Moreover, the two limit cases of the bare frame model (black dashed line) and the damped model without damper failure (i.e., with  $\gamma_\Delta = \gamma_v = \infty$ ) (red solid line) are also analysed for comparison purposes. Two horizontal dotted lines are also depicted in the charts, one identifying the design hazard level  $0.0021 \text{ yr}^{-1}$  (black dotted line) and the other (red dotted line) denoting the target risk level desired for the structural systems ( $2 \times 10^{-4} \text{ yr}^{-1}$ ) [40][41].

With reference to Figure 12 a), it is worth to observe that when the dampers are designed with amplification factors larger than 1.0, the rate of exceeding of the target drift performance ( $IDR=0.012$ ) is around  $0.0021 \text{ yr}^{-1}$ , the hazard level of the design action, with some slight deviations that can be justified by the probabilistic nature of the analysis. Once damper rupture is attained, the building response tends to that of the bare model (black dashed line) and the magnitude of the amplification factors governs the “rapidity” of the transition from the damped to the bare frame curve.

For what concerns the response in terms of absolute accelerations, instead, (Figure 12 b) they are lower than those of the bare frame until the dampers are effective, while they become even higher than that of the bare frame due to end-strokes impacts experienced by the dampers, before their failures for almost all the values of the amplification factors higher than 1.0. In this case also, the magnitude of the amplification factors determines the annual rate probability at which the response tends to become higher than that of the bare frame. Further details concerning the probabilistic analyses results can be found in [30].

Figure 12: Demand hazard curves of (a) IDR and (b)  $A$  for different damper amplification factors. Case of building with linear dampers ( $\alpha = 1.0$ ).

## 6 CONCLUSIONS

The present paper introduces an advanced model which is able to describe the brittle failure of FVDs. Such kind of collapse occurs when the internal force of the device attains its strength capacity and this may occur for two reasons: impact when end-stroke is attained, or attainment of excessive velocity. Both these failure modalities are considered in the analyses.

As a general result, it is observed that combined effects of impacts and extreme velocities may induce a global brittle behaviour that cannot be perceived by models neglecting these phenomena. More specifically, the following conclusions can be drawn:

- The consequences of the damper failure on the performance of a structural system depend on the number of dampers remained active. If all dampers fail together, then the system response in terms of IDR tends to that of the bare building, while the one regarding absolute accelerations may be higher or even worse than that of the bare frame, as a consequence of impacts and dissipation concentrated at some storeys only.
- The magnitude of the amplification factors ( $\gamma_\Delta, \gamma_v$ ) adopted for damper stroke and velocity, governs the “rapidity” of the response transition from damped, or partially damped.
- If no amplification is provided ( $\gamma_v = \gamma_\Delta = 1.0$ ), the dampers probability of failure is higher than the design hazard level (assumed in this work equal to  $0.0021 \text{ yr}^{-1}$ ), thus, dampers experience failure at intensity levels lower than the design one.
- The use of amplification factors higher than 1.0 allows attaining lower failure probabilities, and this beneficial effect is more significant for larger  $\gamma$ -factors.

### Abstract

*Buckling Restrained Braces (BRBs) represent an effective strategy for the seismic retrofit of existing steel Moment Resisting Frames (MRFs), as they contribute to increase the strength, stiffness and energy dissipation capacity of the frame. Nonetheless, the design choices made during the retrofit process have a significant impact on the performance of the structure. For example, the inclusion of 'large' BRBs (i.e., high yielding strength and stiffness) may contribute to limit the deformation demands in the MRF; nonetheless, it may also induce large forces in the beams and columns of the existing structure. On the other hand, the inclusion of 'smaller' BRBs (i.e., low yielding force and stiffness), while allowing reaching the required safety requirements, may not be able to protect the MRF from damage. Additionally, the sizing of the BRB elements has an influence on the seismic demand parameters affecting the global performance of structural and non-structural components (i.e., peak and residual drifts, as well as storey accelerations). The present study investigates the impact of the design choices in the seismic performance of a retrofitted three-storey case-study frame by considering three retrofit options. The case-study MRF for the bare frame and the three retrofit configurations are modelled and numerically investigated in Opensees by monitoring local damage states (e.g., damage in BRBs, beams, columns, panel zones). First, a comparison is made in terms of non-linear static analyses to identify the deficiencies of the structures. Then, a fragility analysis is carried out through Incremental Dynamic Analyses (IDAs) accounting for the influence of the record-to-record variability. Finally, a comparison is made in terms of local and global Engineering Demand Parameters, by developing fragility curves for the components, for storey drifts and accelerations.*

## 1 INTRODUCTION

Buckling Restrained Braces (BRBs) have proven to be effective in improving the seismic performance of existing and new Moment Resisting Frames (MRFs) [1–3]. Such devices can be included within diagonal steel bracing connected to the existing frame contributing to the strength and stiffness of the existing structures by providing a parallel truss-like force path for the seismic lateral load imposed on the building hence forming a dual system [4]. In addition, the stable hysteretic behaviour provided by the BRBs largely contributes towards the increase of the energy dissipation capacity of the structure [2,5]. Similarly to other yielding devices, BRBs rely on the passive dissipation of elasto-plastic energy through the yielding of a steel core, which is surrounded by an unbonded buckling-restraining sleeve that allows the development of significant compression capacity, thus generating nearly symmetrical hysteretic loops [6,7]. In addition, BRBs require low maintenance and can be easily replaced after a strong earthquake, if required.

Regardless of the multiple advantages of BRBs, several aspects require further investigation. For example, the use of BRBs as a retrofit measure for existing steel MRF is followed by a redistribution of load paths and deformation mechanisms, which may induce larger seismic demands on the existing elements [2]. In addition, while the high ductility of BRBs may provide the structure with large energy dissipation capacity, their low post-yielding stiffness may result in large Residual Inter-storey Drift Ratios (RIDRs) [8], hence jeopardising the operativity and repairability of such structures [9–11]. Besides, residual deformations, together with the device's cumulative damage, may also increase the collapse risk under future earthquakes [12].

When properly designed, the MRF can provide restoring forces to counteract the residual drifts related to the yielding of BRBs [4]. Additionally, the Buckling Restrained Braced Frame (BRBF) can contribute towards the reduction of the floor accelerations arising from higher modes effects [4,13] and can limit the damage in the MRF [8]. Nonetheless, the efficiency of this dual system (*i.e.*, MRF + BRBF) is function of the relative properties of the MRF and the BRBF; therefore, the sizing of the bracing system plays a significant role in the effectiveness of the retrofitting scheme.

The present study aims at evaluating the influence of the design choices in the fragility of steel MRFs retrofitted by means of BRBs. First, the assessment of the un-retrofitted case-study structure is performed by comparing deformation-based local Engineering Demand Parameters (EDPs) (*i.e.*, rotations in beams and columns, distortion in panel zones and ductility demand in the BRBs), with the Acceptance Criteria (AC) corresponding to Performance Levels (PLs) as outlined in the ASCE 41-17 [14]. Successively, the design of three retrofitting schemes is carried out considering different design objectives. Then, the bare and retrofitted structures' seismic response is compared by performing both non-linear static and dynamic analysis in an Incremental Dynamic Analyses (IDAs) [15] fashion. The IDAs are performed considering 30 Ground Motion (GM) records allowing the definition of fragility curves. A few preliminary considerations and insights are provided on the influence of the design objectives in the different parameters characterising the seismic performance of structures retrofitted with BRBs.

## 2 CASE-STUDY STRUCTURE AND RETROFITTING SCHEMES

The Boston 3-storey, pre-Northridge MRF designed within the SAC Steel Project [16] has been selected for case-study purposes. This structure is representative of low-code pre-Northridge steel MRFs, as it was designed according to the 12<sup>th</sup> edition of the National Building Code. In this study, the structure is considered to be representative of buildings designed for low seismic demands, which often require retrofitting due to an update in the structural design regulations (*i.e.*, their performance does not comply with new regulations) or those structures

located in regions where design seismic demand was increased as a result of new data on the seismic hazard of the site. The case-study structure was designed assuming stiff soil (Soil Class D in modern standards, *e.g.*, [14,17]), office occupancy, and regular plan distribution and with no considerable irregularities along with the height. In addition, only the perimeter frames are considered to withstand lateral loads (*i.e.*, internal frames are connected as gravity frames only), as it was a common practice in the early 1990s in the United States. Details of the case-study frame are shown in Figure 1.

A 2-D non-linear Finite Element (FE) model of the north-south direction frames is developed in OpenSees [18]. Only this frame is considered in the present study, as the structure is fully symmetric (*i.e.*, torsional effects are negligible). Additional details on the modelling strategy are extensively detailed in Gutiérrez-Urzúa *et al.* [19].

Figure 1: Description of the case-study structure: (a) elevation view of the MRF and location of braces in the retrofitting schemes; (b) plan view of the typical storey floor.

## 2.1 Assessment of the case-study structure

The first and second periods of vibration are  $T_1 = 1.88$  sec and  $T_2 = 0.52$  sec, which is in agreement with previous studies (*i.e.*, [16]). The mode-shape corresponding to the first mode (*i.e.*, [0.29 0.66 1.00]) shows a relatively uniform distribution of mass and stiffness along with the height. Non-linear static analyses, with lateral loads proportional to the first mode-shape and story mass distribution, are performed to evaluate the local components' capacity hierarchy for each PL and to identify the structure's deficiencies. Figure 2 shows the pushover curves for the Inter-storey Drift Ratios (IDRs), including markers for each local component type (*i.e.*, columns, beams and panel zones), to indicate at which points each AC is overpassed. The PLs and AC used in the present study are those defined in the ASCE 41-17 [14]. The green, yellow and red symbols in Figure 2 are related to the Immediate Occupancy (IO), Life Safety (LS) and Collapse Prevention (CP) PLs, respectively. As observed in Figure 2, the failure of the panel zones (square markers in Figure 2) is the first mechanism to occur at all storeys and PLs. For the IO PL the failure of the panel zones is followed by the columns (circle markers in Figure 2) at the first storey and the beams (triangle markers in Figure 2) at the third storey. The system overpasses the IO PL at a roof drift of 0.11 m (corresponding to IDRs of 0.82%, 1.04% and 0.94% for the first, second and third storeys, respectively). Similarly, the LS and CP PLs are reached simultaneously at a roof drift of 0.44 m (corresponding to IDR of 3.61%, 3.96% and 3.46% for the first, second and third storeys, respectively), as the AC for the panel zones is the same in the LS and CP PLs.

Figure 2: Pushover curves for the un-retrofitted structure. Grey lines relate the IDR at each storey to the roof displacement at every 0.05 m.

## 2.2 Buckling Restrained Braces (BRBs) retrofitting design

Three retrofit schemes are designed to comply with different design objectives, expressed in terms of target roof displacements ( $d_u$ ). The first retrofit scheme (R-A) is designed to match the roof displacement at which the first element reaches the CP PL in the MRF structure (panel zones in the first storey, as observed in Figure 2). This represents the design choice where all the resources of the structure are exploited to satisfy the CP requirements. The second retrofit scheme (R-B) is designed based on the roof displacement at which the IDR reaches 2% in any of the storeys, as this is one of the prescribed design limit established by the AISC 341-16 [20] for BRBFs. Finally, the third retrofit scheme (R-C) aims at avoiding damage in the MRF; therefore, the roof displacement is limited to the step at which any of the MRF elements overpasses the IO PL, based on the AC defined by the ASCE 41-17 [14]. Nowadays, there is considerable interest in the definition of seismic-resilient structures (*e.g.*, [11,21,22]) and this third retrofit option aims at limiting the damage to the BRBs only at the CP PL hence allowing an easy and quick reparability of the structure. Table 1 summarises the design limits for the three retrofitting schemes.

Retrofit scheme	Design objective	Target roof displacement, $d_u$
R-A	Avoid the CP PL in the MRF (according to ASCE 41-17 [14])	0.44 m
R-B	Limiting the IDR to 2% in all storeys (according to AISC 341-16 [20])	0.21 m
R-C	Avoid the IO PL in the MRF (according to ASCE 41-17 [14])	0.11 m

Table 1: Target roof displacements ( $d_u$ ) for the considered design objectives.

The design process is carried out by considering an equivalent Single-Degree-of-Freedom (SDoF) system approximation [23], based on the bi-linearised (system base shear vs. roof displacement) capacity curves from the original bare frame, with an initial stiffness ( $k_0$ ) equivalent to the ratio between the 60% of the maximum base shear ( $F_u$ ), and its corresponding roof displacement. The yielding force and displacement ( $F_y$ ,  $d_y$ ) are calculated by considering an equal energy approach (*i.e.*, equal areas under the pushover curves; therefore, defined consistently

with  $k_0$  and  $d_u$ ), and the equivalent SDoF capacity curves are compared to the seismic demands in the acceleration-displacement response spectrum (ADRS) plane.

The seismic demands are calculated considering Seattle as case-study region (corresponding to a moderate seismic region) and following the approach suggested by the ASCE 41-17 [14]. Seismic Risk Category II and stiff soil (Type D) are considered. All the retrofit schemes are designed by considering the BSE-2E hazard provisions (*i.e.*, 5% probability of exceedance in 50 years); nonetheless, the BSE-2N hazard is also considered, as the code requires to use this hazard level as an upper boundary in those cases in which BSE-2E results in higher demands. The response spectra are built aided by the SEAOC's online tool [24], and further modified to consider a 3% damping ratio (*i.e.*, spectra are multiplied by a factor  $B_1$  for BSE-2E and  $B_{SI}$  for BSE-2N, as specified in ASCE 41-17 [14] and ASCE 7-16 [25], respectively). Figure 3 shows the response spectra for the BSE-2E and BSE-2N hazard levels for the 3% damping ratio. As it can be observed, BSE-2N results in lower demands in all periods; therefore, this spectrum is used for the retrofit design in the present study.

Figure 3: Elastic response spectra for the design of retrofit schemes, corresponding to the BSE-2E and BSE-2N hazard levels. BSE-1E and BSE-1N hazards shown for reference purposes.

Figure 4 shows the comparisons between the seismic demand and capacity for the MRF (*i.e.*, the red lines) by considering the three target roof displacements. The comparison shows the inadequacy of the bare frame and hence the need for retrofitting. At the same time, the figures show the seismic demand and capacity for the retrofitted frames (*i.e.*, the dual system) designed such that the capacity is able to meet the demand (*i.e.*, the blue lines). The retrofitted capacity line is the bilinearised form of the trilinear curve composed by the addition of the MRF capacity line and the BRBF capacity line (*i.e.*, the purple line). The ductility-reduced demands [23] are obtained after bi-linearisation of the systems.

The MRF ductility ( $\mu_{MRF}$ ) is equal to 3.32, 1.74 and 1.17 for the R-A, R-B and R-C schemes, respectively, while the BRBF ductility ( $\mu_{BRBF}$ ) is designed as 18, 14 and 8. The resulting system ductility ( $\mu_{DS}$ ), defined as the ratio between the ultimate and yielding displacements in the dual system bilinearised curve ( $d_u/d_y$ ), is equal to 4.74, 4.28 and 4.40. In order to match the BRBF stiffness and ductility requirements, the SDoF is de-coupled by considering the original mode shape of the structure, therefore, defining the design requirements at each storey. Finally, the area and length of the BRBs is defined in accordance to the force and ductility requirements for the storey, while the area in the complementing elastic brace is defined in accordance with the stiffness requirements of the storey (*i.e.*, with the elastic brace and BRB working in series). For a more in-depth discussion on the design method, the reader is referred to Freddi *et al.* [26].

The nominal material yield strength ( $f_y$ ) considered for the BRBs, correspond to steel ASTM A36 ( $f_y = 248$  MPa), which is further increased by 30% for the design, to represent the expected

yield strength ( $f_{ye}$ ) of the material, based on the ratios provided by the AISC 341-16 [20]. The design ductility ( $\mu_{BRB}$ ) of the BRB material is 20, which is within (and consistent with) the ranges observed in previous experimental work [27]. The elastic braces are made in steel ASTM A500 Grade C ( $f_y = 317$  MPa).

The BRBs are modelled in Opensees [18] by using the *SteelBRB* material [5], while the elastic braces are modelled by considering the *Elastic* material, as they are not expected to yield at any point due to the lower strength in the connected BRBs. Table 2 shows a summary of the BRB properties for each retrofitting scheme.

Figure 4: Bi-linearised pushover curves of the equivalent SDOF bare and retrofitted structures, in comparison with the demands, presented in the displacement-acceleration response spectrum (ADRS) plane.

Model	Storey	BRB device		Elastic brace	
		Area [mm <sup>2</sup> ]	Length [m]	Area [mm <sup>2</sup> ]	Length [m]
R-A	1	1301	2.96	11542	3.09
	2	1115	3.75	5813	2.30
	3	693	3.47	4385	2.58
R-B	1	5204	1.41	37167	4.64
	2	4460	1.78	23109	4.27
	3	2771	1.08	16017	4.97
R-C	1	11710	0.70	52383	5.35
	2	10034	0.58	34204	5.47
	3	6236	0.54	23280	5.51

### 3 ASSESSMENT OF THE RETROFITTED CASE-STUDY STRUCTURES

After the retrofitting of the case-study building, the structure's fundamental period is reduced from 1.88 s, for the bare frame, to 1.06 s, 0.60 s and 0.50 s for R-A, R-B and R-C, respectively. Non-linear static analyses are performed on the retrofitted structures, and the AC thresholds for all the structural PLs established in ASCE 41-17 [14] are monitored and shown in Figure 5. For BRBs, the AC is expressed in terms of plastic deformations and the CP PL is increased from 13.3 to 19 times the yielding deformation, as this value is consistent with the design ductility of 20.

In the case of R-A, shown in Figure 5a, the structure's improvement allows reaching base shear values over 2000 kN, with PLs that are first overpassed by the BRBs at all storeys. However, the PLs for the panel zones in the IO and CP PLs, closely follows, highlighting the

adequacy of the design strategy in terms of the distribution of the devices stiffness and strength. In addition, when the structure reaches a CP PL, columns in the bottom storey are considered to experience structural damage, as their IO PL is overpassed. In the case of R-B, shown in Figure 5b, the pushover curves show higher post-yielding stiffness due to the hardening of the BRBs, which provide a larger base shear contribution in this configuration. BRBs control the system failure for all PLs; nonetheless, panel zones reach the IO PL when the BRBs overpass the LS PL, which suggests that the MRF exhibits damage whenever the BRBs overpass this PL. Finally, the case R-C, is shown in Figure 5c. In this case the strength and stiffness contribution of the BRBs is significantly higher, while the BRBs reach the CP LS almost as the panel zones reach the IO LS, which suggests that the MRF remains undamaged while the BRBs reaches its considered failure. It is worth mentioning that the damage scenario observed is consistent with the design objectives which are also represented by the lines for the design displacement  $d_u$  (*i.e.*, the blue dotted lines) in Figure 5.

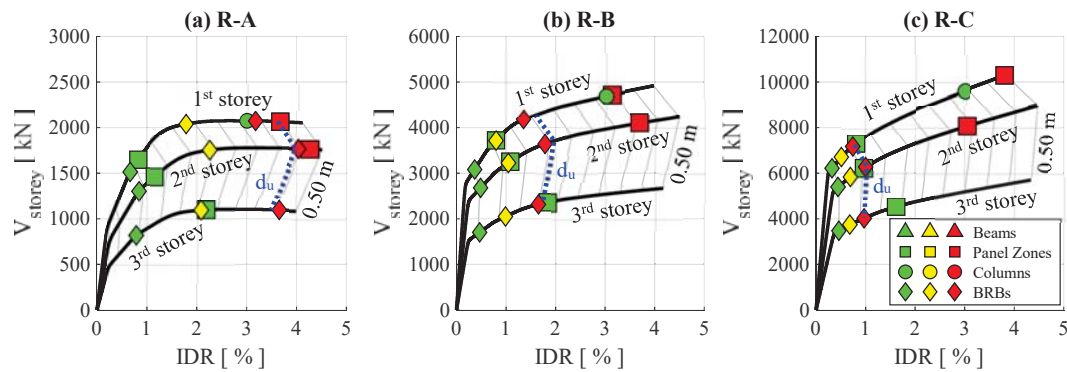

Figure 5: Pushover curves for the retrofitted structures. Grey lines relate the IDR at each storey to the roof displacement at every 0.05 m.

### 3.1 Fragility of the case-study structure and retrofitting schemes

The fragility of the bare and retrofitted structures is derived based on IDAs [15] by considering a set of 30 GM records selected from the PEER NGA-West2 database [28]. These GMs are selected to be in agreement with the BSE-2N spectrum (see Figure 3), with no further discrimination (all types, with no distinction for distances, wave velocities nor significant duration). Only the acceleration in the  $x$ -direction is considered.

Based on the results of the IDAs, fragility curves are derived. These provide the probability of the Damage State (DS) exceeding a specific PL in a component (or in the system), conditional to the value of the intensity measure (IM), *i.e.*,  $P(DS \geq PL | IM)$ . DSs are defined by the the seismic deformation demands and compared to the capacity (*i.e.*, the element-based AC related to a PL) for all the considered components. The spectral acceleration corresponding to the structure's fundamental period  $S_a(T_1)$  is considered as IM [29] in the present study.

The fragility curves for the bare and retrofitted case-study structures are shown in Figure 6. These curves are derived for each element type (*e.g.*, BRBs, columns, beams and panel zones), while the system fragility is defined by considering a series arrangement of the components, *i.e.*, corresponds to the first element (of any kind) to overpass the AC for the considered PL. In addition, fragility curves are built for those cases in which the numerical model does not reach convergence due to excessive deformation (*i.e.*, collapse cases, as defined by Jalayer *et al.*) [30]. Nonetheless, these cases occur once the element-based AC is overpassed in all PLs, therefore, they are simply treated as collapse cases.

Consistently with the observations from the pushover analyses, the panel zones define the system fragility for the bare frame, while the BRBs define the system fragility in the retrofitted cases, *i.e.*, they represent the most fragile components for the whole range of IM values. The direct comparison of fragility curves for the different retrofitting schemes allows to synthetically contrast the capacity of the retrofitting schemes, however, it should be noted that it does not allow to consider the demand changes due to the period shifting, therefore, a comprehensive comparison requires site-dependent hazard considerations.

As it can be observed, the increase of capacity is reflected in the shifting of the fragility curves to higher IM values, accordingly with the retrofitting level. The median intensity values ( $IM_{50}$ ) of the retrofitted structures are increased by 136%, 255% and 445% for the R-A, R-B and R-C retrofitting schemes for the IO PL; by 54%, 80% and 100% for the LS PL; and by 159%, 184% and 207% for the CP LS. The effect of the record-to-record variability is more noticeable in the retrofitting scheme R-A when compared to R-B and R-C, as reflected by the lognormal standard deviation  $\beta$  values. This effect may be related to the larger ductility of the BRBF in the R-A retrofitting scheme, as highlighted by Freddi *et al.* [4]. It is relevant to highlight that all force-controlled failures (*e.g.*, compression/tension in columns, shear in beams) occur after all the PLs are overpassed, therefore, they do not influence the fragility curves.

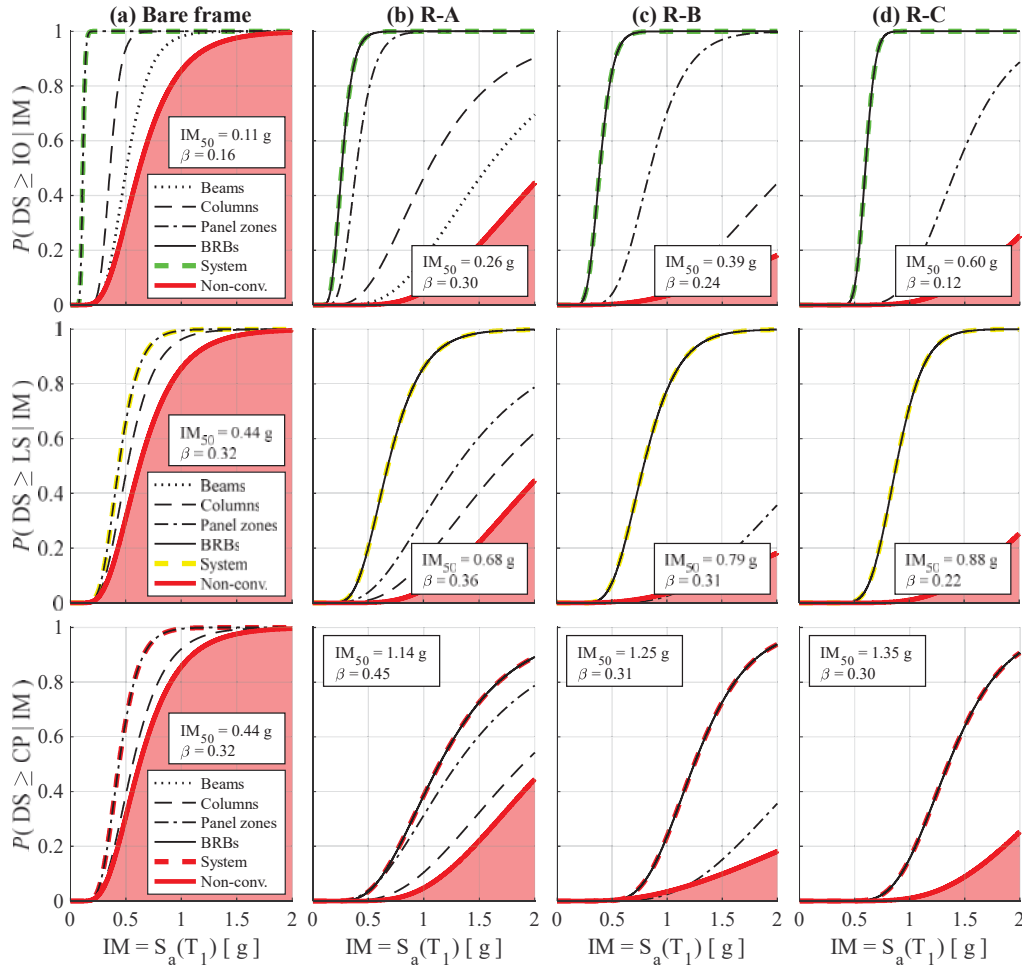

Figure 6: Element-based fragility curves for the IO, LS and CP PLs. The parameters  $IM_{50}$  and  $\beta$  are shown for each system fragility curve.

Finally, for comparison purposes only, Figure 7 shows the fragility curves for the monitored global EDPs, which include the Peak Inter-storey Drift Ratios (PIDRs), the Residual Inter-storey Drift Ratios (RIDRs) and Peak Storey Accelerations (PSAs). The AC thresholds for the PIDR of 0.5%, 1.5%, and 2%, suggested by the ASCE 41-06 [31] for braced frames, respectively for IO, LS and CP PLs have been assumed in this study. For the RIDR, an AC thresholds of 0.5% is used, in accordance with McCormick *et al.* [9], which was defined with the aim of controlling building reparability. Finally, the AC thresholds for PSA have been assumed based on the limits used by the Hazus-MH MR4 Technical Manual [32] for moderate-code structures, corresponding to 0.5g, 1.0g and 2.0g for the Moderate, Extensive and Complete PLs.

As shown in Figure 7, the median (*i.e.*,  $IM_{50}$ ) values for the PIDR and the RIDR fragility curves are increased as the stiffness of the structure is increased, as expected. In the case of the  $IM_{50}$  for the PSA fragility curves, all the retrofitting schemes exhibit similar values for the first two thresholds (*i.e.*, 0.5g, 1.0g); however, when the largest acceleration threshold (*i.e.*, 2.0g) is considered, the stiffest structures exhibit larger  $IM_{50}$  values. Similarly to the element-based fragility curves, the  $\beta$  parameter is larger in the retrofitting schemes with larger ductility in the BRBF. Also, the dispersion is observed to be larger for the RIDR and PSA fragility curves.

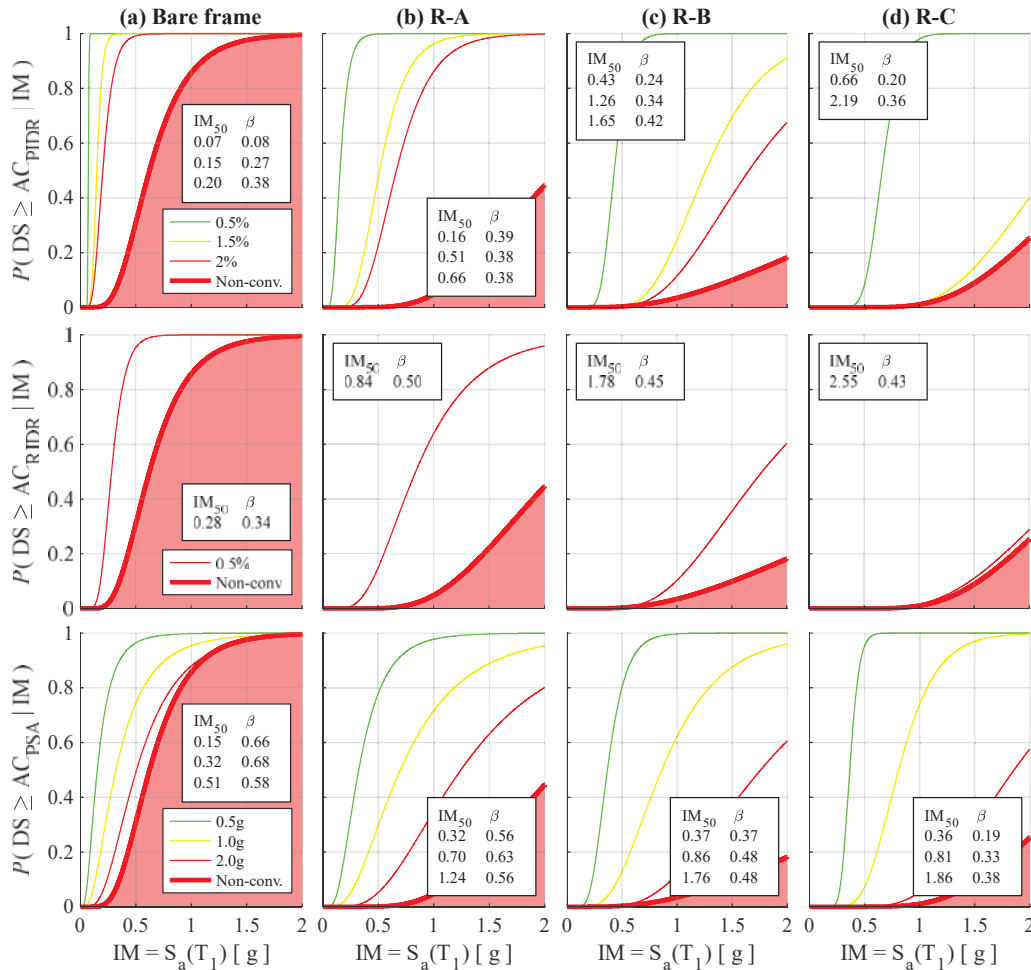

Figure 7: Global fragility curves for the peak inter-storey drift ratios -PIDR- (top), residual inter-storey drift ratios -RIDR- (middle) and peak storey accelerations -PSA- (bottom), for different performance limits (PLs).

#### 4 CONCLUSIONS

This paper presented the fragility assessment of a case-study steel Moment Resisting Frame (MRF) retrofitted with Buckling Restrained Braces (BRBs). Three retrofit configurations were considered which aimed at achieving different performance levels (PLs): R-A was designed to protect the MRF elements from reaching the Collapse Prevention (CP) Performance Limit (PL); R-B was designed to avoid a Peak Inter-storey Drift Ratio larger than 2% at any storey; while R-C was designed to protect the MRF elements from reaching the Immediate Occupancy (IO) PL. The assessment of the bare frame and of the three retrofitting solutions was carried out both by pushover analyses and by Incremental Dynamic Analyses (IDAs). IDAs were performed by using a set of 30 Ground Motion (GM) records, and fragility curves were successively derived by considering limits for element-based and global Engineering Demand Parameters (EDPs).

The following conclusions can be drawn:

- The R-A fragility was controlled by the BRBs in all PLs, closely followed by the panel zones in the IO and CP PLs. In the R-B scheme, the BRBs were capable of protecting the MRF from damage (*i.e.*, overpassing the IO PL) up to a Life Safety (LS) PL in the BRBs. Finally, the R-C scheme was capable of protecting the MRF from damage up to a CP PL, as originally intended during the retrofitting design. These observations are made based on both the non-linear static and the fragility assessments.
- In the case of the global EDPs, the retrofitted structures exhibited a lower probability of exceeding the PLs for all the values of intensity measure (IM), when compared to the bare frame. The stiffer retrofitting schemes were capable of reducing the Peak and Residual Inter-storey Drift Ratios (PIDR and RIDR) for all the values of IM. Conversely, for Peak Storey Acceleration (PSA), the fragility curves derived by considering low acceleration limits (*e.g.*, 0.5g and 1.0g) is similar for all retrofitting schemes. For larger limits of acceleration (*e.g.*, 2.0g), the probability of exceedance is reduced for all values of IM in the stiffer retrofitting schemes (*i.e.*, R-B and R-C).
- In all fragility curves, the dispersion of the distribution (represented by the lognormal standard deviation,  $\beta$ ) is increased in structures with larger ductility (*e.g.*, R-A) while it is reduced in structures with lower ductility (*e.g.*, R-C). In all cases, the fragility curves for the RIDR and the PSA exhibit larger  $\beta$  values, in comparison to other EDPs. This is consistent with other studies present in the literature.
- Despite the increase of axial demands in the column and beam elements due to the trussing effects provided by the braces, none of the retrofitting schemes exhibited force-controlled failures in these elements earlier than any of the deformation-controlled acceptance criteria (AC) defined.
- In general, the median capacity (represented by  $IM_{50}$ ) of the retrofitted structures was benefited from larger retrofitting options, in particular, when large PLs are considered as limits (*e.g.*, CP). The dispersion of the fragility distribution ( $\beta$ ) generally increased when considering higher PLs, as well as when considering the RIDR and PSA in comparison with other EDPs. In addition, larger values of  $\beta$  were observed when the Buckling Restrained Braced Frames (BRBFs) within the dual systems were designed for larger ductility targets (*e.g.* R-A).

It is noteworthy that the comparison in terms of fragility only does not provide information on the retrofit's effectiveness, as it considers the variation of the capacity alone. Future work is required toward the inclusions of considerations related to the seismic demand variation for the different retrofit options (*e.g.*, risk definition).

### Abstract

*Seismic isolation is a mature and effective method of reducing earthquake-induced building damage. However, applications of this technology are limited to special and important structures, predominantly in the developed world, due to the associated high costs.*

*An experimental study of a spherical rubber seismic isolator is presented herein. The cost of these devices is sufficiently low that their wide-spread application in low-income countries seems economically viable. Using a closely spaced grid of such spheres may require only a thin, lightly-reinforced diaphragm slab above the isolation level, further reducing construction costs. Avoiding the cost of this extra slab is crucial to make seismically isolated low-rise buildings economically feasible in poor regions of the globe.*

*The examined seismic isolation bearings are based on rolling, with rubber spheres rolling on concave (spherical) or flat concrete surfaces. Concave concrete surfaces provide restoring force to the isolated structure through gravity. In contrast, in the case of flat concrete surfaces, no restoring force is applied. Rubber spheres offer increased damping and better stress distribution in the contact areas than spheres made using stiffer materials. This work investigated the effects of the geometry of the rolling surface (i.e., flat or concave), the diameter of the rolling sphere (i.e., 50 or 100 mm), and the applied compressive load on the seismic behavior of these isolation bearings. Initially, the rubber isolators were subjected to monotonic uniaxial compression to examine their behavior under vertical loading. Subsequently, cyclic tests were performed to obtain the lateral force-displacement diagram of the isolation system. It was found that the coefficient of rolling friction depends on the axial load, and the diameter of the spheres. The governing parameter for the design of the rubber spheres is not material failure, but excessive compressive deformation that leads to undesirably high rolling friction. Overall, experimental results proved the efficiency of the investigated system in terms of decreasing the inertia forces transmitted to the superstructure.*

## 1 INTRODUCTION

Seismic isolation [1,2] is a seismic response modification technique, which uncouples the motion of the structure from the ground shaking. This is achieved by placing a low-stiffness or slippery layer at the base of the structure. This elongates the dominant eigenperiod of the structure, reducing the applied accelerations and, thus, the inertial forces. The main drawback is that it leads to increased displacements; however, these displacements are localized at the isolation level, with the interstory drifts maintaining low values. The three key concepts that a seismic isolation scheme should fulfill are: i) Sufficient bearing capacity under vertical (gravity) loads, ii) sufficient flexibility in the horizontal direction to uncouple the motion of the structure from the ground motion, iii) energy dissipation [3]. An important design consideration is that, when seismic isolation is used, the superstructure should be designed to remain essentially elastic. Previous studies [4,5] proved that this is not a conservative design, but a necessity, emerging from the dynamics of base-isolated structures.

Modern applications of rolling seismic isolation systems focused on isolation of precious equipment, where the supported mass is expected to be low. The rolling spheres were mainly made of steel or rubber, and the supporting plates were made of concrete or steel [6-10]. The geometry of the supporting plates was either conical or concave, providing restoring force through gravity. Even though the efficiency of isolation devices is acknowledged, the implementation of these technologies is limited due to the associated high cost. The high cost originates from a) the cost of the isolation devices and b) the cost of the extra slab required at the isolation level. Finally, the high weight of these devices (can reach 1 ton per device) demands the use of lifting equipment, further increasing the complexity of the construction [11]. There have been numerous attempts to reduce the cost of seismic isolation devices [12-27, among others].

This work focuses on the recently published work by Cilsalar and Constantinou [28-30], who essentially suggested a Friction Pendulum System (FPS bearing) based on rolling instead of sliding (Figure 1). It comprises two concrete surfaces and a stiff rubber sphere (with or without a steel core) that rolls in between. The system is indeed low-cost, as the rubber balls can be obtained for low price. However, it still requires an extra slab above the isolation devices – hence, the overall cost still remains prohibitive for low-rise buildings in low-income countries. This paper suggests the use of a grid of closely-spaced rubber spheres. Using a grid could allow the construction of a thin, lightly reinforced diaphragm, reducing the construction cost (Figure 2). Moreover, since several spheres are used, each sphere supports a lower vertical force (weight); therefore, one could use spheres with smaller diameter, made of rubber material of lower stiffness, and without a steel core.

Figure 1: Low-cost rubber rolling isolator, tested by Cilsalar and Constantinou [28-30].

Figure 2: Schematic representation of the low-cost seismic isolation proposed in the present study.

This study presents the compressive and cyclic behavior of low-cost rolling rubber isolators. The cyclic behavior is quantified using a half-scale system of four isolators, capped with a slab. Parameters of investigation are the diameter of the rubber sphere (i.e., 50 mm or 100 mm), the geometry of the concrete plate (i.e., flat or concave), and the supported weight (i.e., 2.08 kN, 3.23 kN or 4.74 kN).

## 2 EXPERIMENTAL SETUP

### 2.1 Testing equipment and instrumentation

Cyclic tests were performed using the shake table of the ETH [31] as an actuator. The shake table is a stiff steel box with dimensions of 1 x 2 m, operated by a servo-hydraulic actuator of 100 kN, which acts only in one direction. The stroke, maximum velocity, and maximum payload is 240 mm, 220 mm/second, and 7.5 tons, respectively. Before testing, the accuracy of the shake table was assessed by performing preliminary tests and comparing the applied to the expected motion, with the two being closely correlated.

The experimental setup is shown in Figures 3 and 4. Four isolators (i.e., four pairs of concrete plates) were placed on top of the shake table. A 30mm-thick steel slab was mounted on the top plates, and weight was placed on top of it. The slab was connected to a stiff column via two rigid struts to constrain its motion along the table axis ( $x$ ) and around the vertical axis ( $z$ ). Side stoppers and a rail in the middle prevented the slab from moving out of plane. Variable weight in the form of steel beams was placed on top of the structure to apply vertical load on the bearings. In all configurations, the bottom concrete plates were flat. In some configurations, hereafter characterized as “concave,” the top rolling surfaces were spherical.

The plates were made of unreinforced concrete with fine aggregate since steel reinforcement increases cost and construction time, making implementation harder in developing countries. The geometry of the plates is shown in Figure 5.

The radius of curvature of the concave concrete plates ( $R$ ) was  $R = 750$  mm. In plan view, the diameter of the concave concrete plate was 350mm. A commercial low-cost M15 concrete mix was selected, with a maximum aggregate size of 4 mm. The mean compressive and flexural strength was equal to 27.62 MPa, and 4.63 MPa, respectively, tested according to EN 1015-11 (1993) [32]. The utilized rubber spheres were made of natural rubber (NR), with a

shore hardness of 85A. The cost of the 50 mm and 100 mm diameter spheres was 3 \$ and 17\$, respectively [33].

## 2.2 Tested configurations and similitude laws

Walls of modern unconfined masonry houses in Cuba weight  $2.80 \text{ kN/m}^2$ . Assuming a wall height of 2.8m, gives an unfactored weight of the masonry wall of  $7.8 \text{ kN/m}$ . A 10 cm roof slab at a typical  $5 \times 5 \text{ m}$  room would add  $3 \text{ kN/m}$  to each wall, giving a total weight of  $11 \text{ kN/m}$ . Assuming isolators placed every 1 m, the vertical load of each isolator is  $11 \text{ kN}$ .

The tests were designed assuming a geometrical scaling of  $S_L = 1:2 = 0.5$ . Therefore, to preserve similitude of stresses the force scaling factor is  $S_F = S_L^{-2} = 4$  [34].

Rubber spheres of 50 and 100mm diameter were tested. Three compressive loads (2.08 kN, 3.23 kN or 4.74 kN per sphere in the model scale) under 2 rolling surface geometries (flat/flat and flat/concave) were planned. This corresponds to a total number of 12 configurations. However, due to a limitation of the experimental setup, the spheres with a diameter of 50 mm were tested only with flat concrete plates and with the lower two weight configurations (2.08 kN and 3.23 kN per sphere). A summary of the tested configurations appears in Table 1. Table 2 summarizes the relevant quantities in the model and prototype scale.

Weight per sphere (kN)	Geometry of Concrete Plates	Diameter of Rubber Spheres (mm)	
		100	50
2.08	Flat	Tested	Tested
	Concave	Tested	Not tested
3.23	Flat	Tested	Tested
	Concave	Tested	Not tested
4.74	Flat	Tested	Not tested
	Concave	Tested	Not tested

Table 1: Summary of the tested configurations

Quantity	Model Scale	Prototype Scale
Radius of concave concrete plates	750 mm	1500 mm
Eigenperiod of concave concrete plates	1.74 sec	2.46 sec
Plan view diameter of the concave isolator	350 mm	700 mm
Diameter of large rubber spheres	100 mm	200 mm
Diameter of small rubber spheres	50 mm	100 mm
Vertical load	2.08, 3.23, 4.74 kN	8.32, 12.92, 18.96 kN
Amplitude of cyclic test	$\pm 100$ mm	$\pm 200$ mm

Table 2: Summary of the main quantities of the experimental model and the corresponding prototype structure

### 3 TEST RESULTS

#### 3.1 COMPRESSION TESTS

The first part of the experimental investigation comprised monotonic uniaxial compression tests to characterize the response of the rubber spheres under vertical loading (Figure 6). The compression tests were conducted using displacement control. This corresponds to a displacement rate of 0.33 mm/sec and 0.167 mm/sec for the rubber spheres with a diameter of 100 mm and 50 mm, respectively. The compression tests revealed that material failure is not a critical design parameter, since the utilized spheres can sustain very high vertical load, without material failure. The critical design parameter is expected to be the excessive deformation and the associated shape change. Under high vertical loading, the shape of the rolling rubber isolators is no longer spherical; thus, the rolling friction coefficient (i.e., the ratio of horizontal-to-vertical force to initiate rolling) reaches high values.

Figure 6. Results of the compression tests of rubber spheres; Left: full view of the tests; Right: Detailed view for the load levels that correspond to the configurations tested in the cyclic tests

#### 3.2 CYCLIC TESTS

The second part of the experimental procedure comprised cyclic testing of the various configurations of rolling isolators. All configurations were subjected to sinusoidal displacement, with an amplitude of 100 mm and a frequency of 0.2 Hz. The isolators were subjected to at

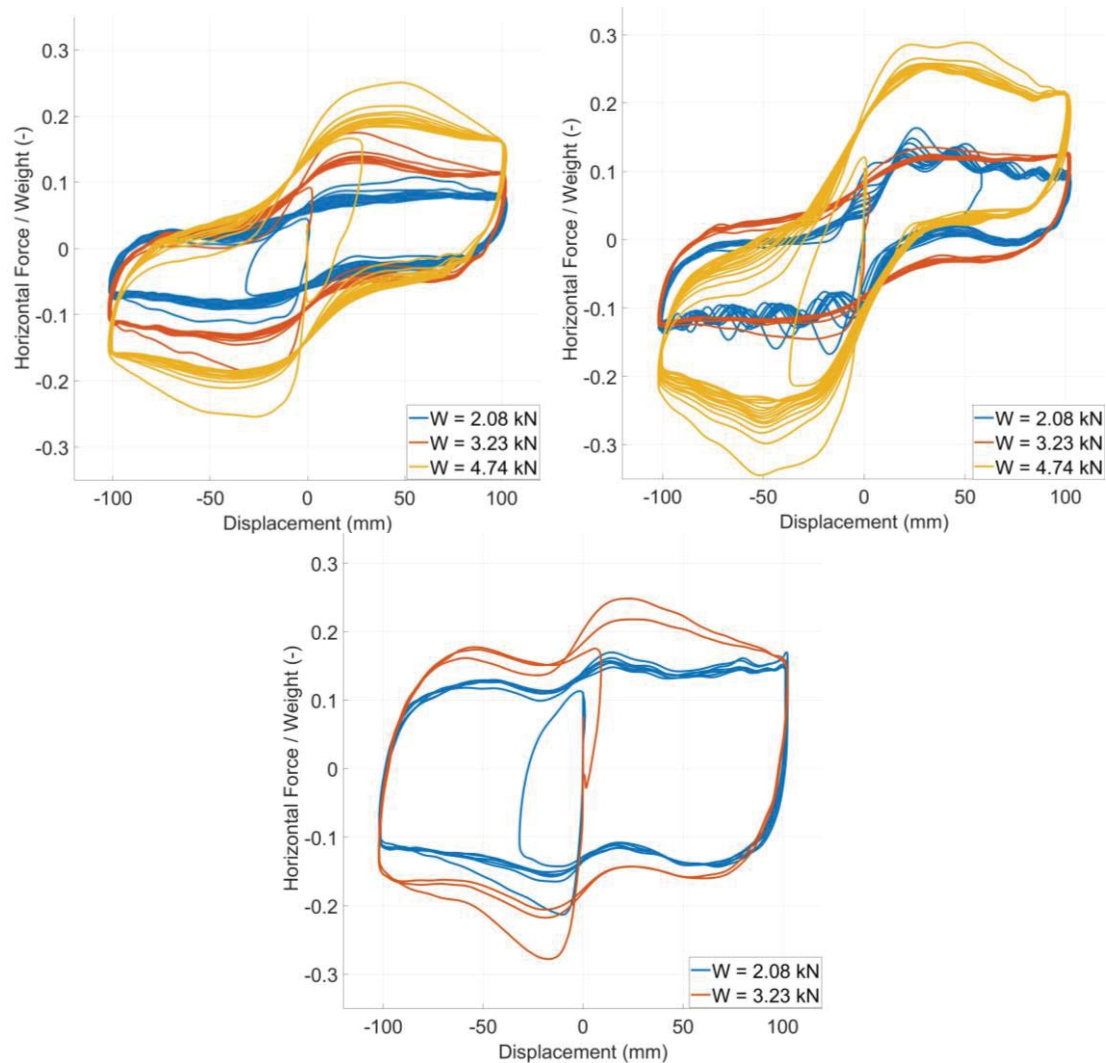

Figure 7. Influence of the vertical load on the cyclic response. Top-left: Spheres with a diameter of 100 mm and flat concrete plates, Top-right: Spheres with a diameter of 100 mm and one concave concrete plate, Bottom: Spheres with a diameter of 50 mm and flat concrete plates

least three cyclic loops, whereas in some cases, more cycles were applied to investigate the possible deterioration of the rolling spheres. All spheres were preloaded for seven days before testing with a load equal to the load they supported during cyclic testing, so that much of their creep is completed.

Figures 7 and 8 present normalized force – deformation loops for different vertical loads. The rolling friction coefficient is defined as  $\mu = Q/W$ , where  $Q$  is the force at zero displacement and  $W$  is the weight carried by the bearings. An increase of the vertical load or a reduction of the diameter of the sphere leads to an increased rolling friction coefficient. Moreover, the ratio of the horizontal-to-vertical force increases for all levels of displacement, with the isolation system dissipating more energy (i.e., larger area included in the cyclic loops).

During the first cycle, the spheres exhibit slightly stiffer behavior, whereas after the second cycle, the loop becomes stable, and no further softening is observed. Figure 9 compares the response of flat and concave bearings. Unexpectedly, they exhibit a similar behavior. A possible explanation is that 7 days of creep have resulted in the rubber spheres taking an oval shape that is maintained for the loading rate of the tests. Stiffness originates from the rise of the top plates as the isolator is sheared. It seems that the rise due to the oval shape of the rubber is more important than the one because of the spherical shape of one of the plates. Note,

that the applied displacements cause rotations equal to only  $57.3^\circ$  and  $114.6^\circ$  on the 100mm and 50mm spheres respectively, that is they do not make even half of a full turn. Hence, to explore the behavior at larger displacements, an extrapolation cannot be performed and more tests are needed.

It is worth noting that some cyclic plots include negative-stiffness branches, which are either monotonic or alternating with positive-stiffness branches. These observations are consistent with the observations of Cui et al [6], who tested similar isolators under lower vertical load levels.

Finally, one of the cyclic plots ( $W = 2.08$  kN,  $D = 100$  mm, Flat concrete plates) demonstrated significant fluctuations, with these fluctuations being consistent over the cycles. Similar behavior has been observed by Nikfar and Konstantinidis [35] in tests of equipment supported on caster tires and is called “flat spotting” and they require further study.

In all cases, the rolling friction coefficient maintained low values, sufficient for seismic isolation applications. A summary of the rolling friction coefficient for each case appears in table 3. The coefficient of friction will be reduced if harder rubber is used.

## 4 CONCLUSIONS

This paper presents an experimental study on the cyclic and compressive response of low-cost bearings comprising balls rolling on concrete surfaces. Placing the spheres below the walls of the structure at a dense grid would only require the construction of a thin, lightly-reinforced isolation diaphragm, instead of the massive slab that is now required. This is crucial to make seismic isolation affordable in low-income countries.

A half-scale model of prototype bearings was tested, comprising four isolators capped with a slab. Parameters of investigation were the vertical force on each rolling isolator (i.e., 2.08 kN, 3.23 kN, or 4.74 kN), the geometry of the rolling surface (i.e., flat or concave) and the diameter of the rolling sphere (i.e., 50 mm or 100 mm).

Figure 8. Influence of the diameter of the spheres on the cyclic response, using flat concrete plates. Left: Vertical load of 2.08 kN, Right: Vertical load of 3.23 kN

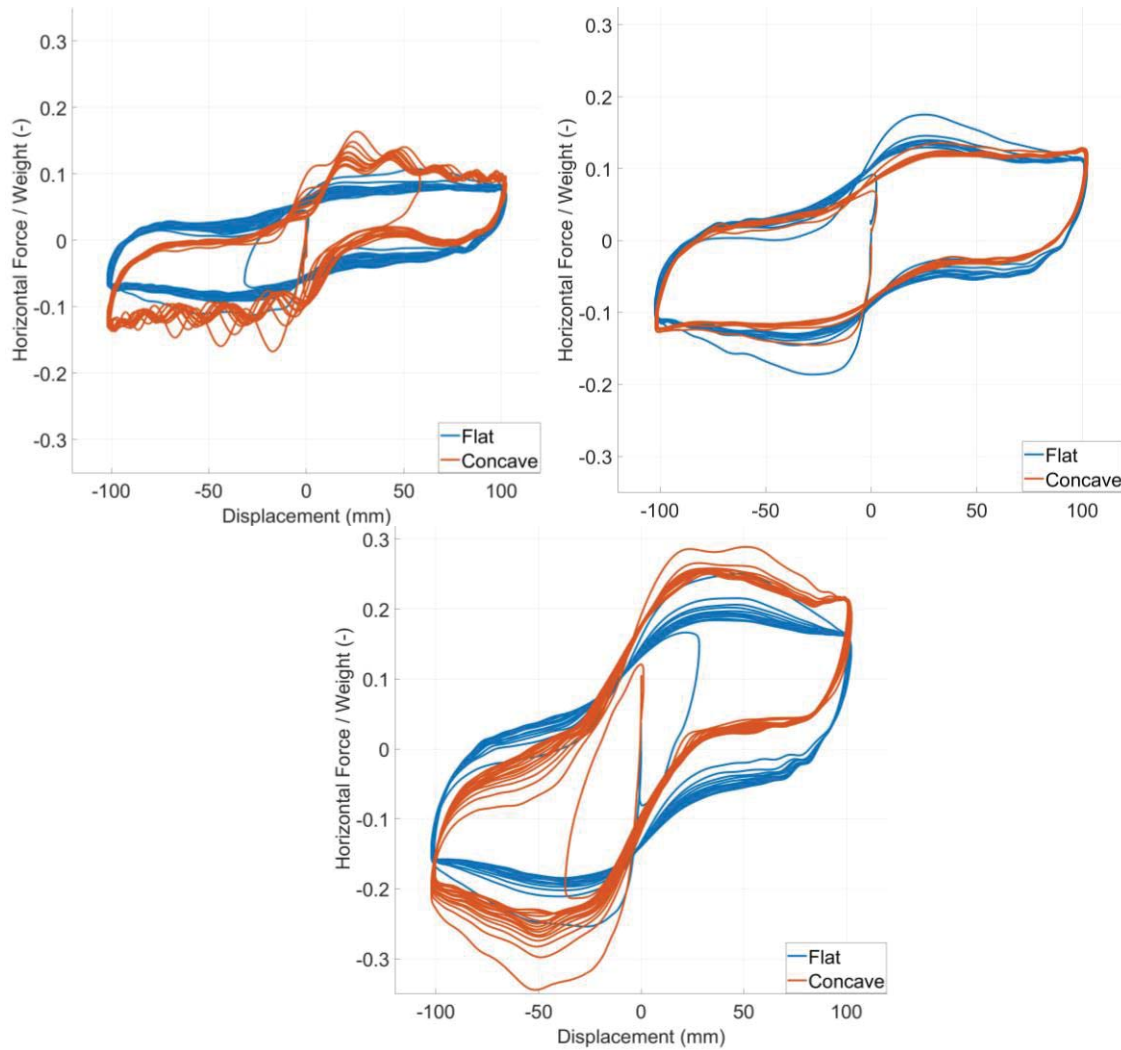

Figure 9. Influence of the geometry of the concrete plates on the cyclic response of spheres with a diameter of 100mm. Top-left: Vertical load of 2.08 kN, Top-right: Vertical load of 3.23 kN, Bottom: Vertical load of 4.74 kN

Diameter of Rubber Sphere (mm)	Vertical Load (kN)	Concrete Plate	Rolling Friction Coefficient (%)
100	2.08	Flat	6.1
		Concave	7.1
	3.23	Flat	8.9
		Concave	8.2
	4.74	Flat	13.7
		Concave	10.7
50	2.08	Flat	13.2
	3.23	Flat	17.6

Table 3: Summary of the rolling friction coefficient of the various tested configurations

Vertical loads up to a representative value for low-rise masonry building in the developing world were applied. Experimental results proved the efficiency of the investigated system in reducing the inertia forces transmitted to the superstructure, with the rolling friction coeffi-

cient (i.e., the ratio of horizontal to vertical force at zero displacement) being in the range of 6.1-17.6 %, thus, suitable for seismic isolation applications.

An increase in the vertical load or a reduction of the size of the sphere leads to a more deformed shape of the isolator, hence, to an increased rolling friction coefficient.

For the displacements considered, the influence of the concrete plate (i.e., flat or concave) is marginal since the deformed shape of the rolling isolator dominates the response. More tests are needed to understand the behavior of the system at larger displacements.

### Abstract

*In recent years, post-tensioned timber framed buildings, recognized as one of the most effective sustainable and anti-seismic solutions, are developing throughout the world. Post-tensioning (PT) loss in timber framed buildings with post-tensioned beam to column joints is a crucial aspect which governs the moment capacity of the connection and the global seismic performance of the frame.*

*This paper investigates on the variations of the post-tensioning force of a 2/3 scaled, three-storey, post-tensioned timber frame experimental model investigated in three different configurations: bare frame; with dissipative rocking mechanism; with dissipative bracing system. The variation of post-tensioning during shaking table testing a set of seven spectra-compatible earthquakes at increasing PGA levels has been evaluated and the long-term losses over about four years have been investigated.*

**Keywords:** Post-tensioned timber framed buildings, Energy dissipation systems, Shaking table tests, Post-tensioning variation.

## 1 INTRODUCTION

In recent years, Europe Union strategies and worldwide policies are moving towards the reduction of greenhouse gas emissions and there is an increased trend to reconsider timber as construction material for multi-storey buildings optimizing the structural concept and the seismic design, with the dual purpose to obtain more sustainable and anti-seismic constructions. In order to mitigate seismic risk and significantly reduce structural and non-structural damage avoiding high economic loss, in the last decades research studies focused on low damage design and technologies.

Recent advancement in earthquake engineering have led to the development of a pre-stressed laminated (Pres-Lam) technology for timber constructions. The system, originally conceived by Priestley et al. (PRESSS) [1] for precast concrete frame and wall constructions, was successfully applied to create timber jointed ductile connections [2]. It consists in the use of high strength unbounded steel cables or bars to connect timber beams and columns, or walls to their foundations, providing self-centering capability to the frame. In order to increase the seismic performance additional internal or external dampers could be added to the joints, to provide additional strength and energy dissipation capability. During the rocking motion due to earthquake or other horizontal loads, a gap opening (and connection rotation  $\theta$ ) is produced, as shown in Figure 1 for the beam-column joint, activating the elongation of the unbounded post-tensioned bar ( $F_{PT} + \Delta F_{PT}$ ) and the yielding of the additional hysteretic dissipation devices ( $F_y$ ). The introduction of external metallic yielding dampers represents an optimal low-cost solution requiring a little maintenance and easily replaceable in case of damage. The combination of the moment capacity due to post-tensioning  $M_{PT}$  (bilinear elastic response) and to yielding of steel devices  $M_s$  (hysteretic response), provide the total moment capacity  $M_t = M_{PT} + M_s$ . This hybrid system allows to obtain damage-avoiding structures characterized by the typical flag-shaped response with the capability to absorb energy in a major earthquake while rocking back to an undamaged position after the shaking, resulting in negligible residual drift.

Figure 1: Undeformed configuration and post-tensioning stresses during the seismic motion of the beam-column joint.

A crucial aspect in timber building is represented by the long term rheological effects, such as creep phenomena due to permanent loads, which can affect serviceability and structural integrity of the building. The long-term performance of post-tensioned timber systems is of interest, particularly regarding tension loss in the steel cables or bars, which can lead to reduction of the moment capacity of the connection, affecting recentering capabilities and the global seismic performance of the frame [3]. Moreover, the relationship with environmental loads and creep behavior of the timber elements contribute to post-tensioning loss [4] and the horizontal motions of timber buildings can be monitored to detect residual drifts after a seismic event. To date, few research study on the post-tensioning losses of this

recent timber construction system are available in literature. Recent experimental and analytical studies [5]-[6] on post-tensioning loss deriving from creep phenomena in compressed timber elements were performed in New Zealand and Switzerland. The results showed expected losses in the range of 6-50% in 50 years in various real monitored building, such as the Trimble Navigation Offices (NZ) and the House of Natural Resources (Switzerland), mainly depending on the ratio between post-tensioning steel and timber and on the amount of timber loaded perpendicular to the grain [7].

This paper focuses on seismic post-tensioning variations and on long-term losses evaluated on a 2/3 scaled, three-storey, post-tensioned timber frame experimental model tested at the structural laboratory of University of Basilicata (Italy), in collaboration with University of Canterbury (New Zealand) [8]. The experimental model was investigated in different testing configuration with increasing amount of energy dissipation and the tension losses were monitored over about four years.

## 2 EXPERIMENTAL MODEL

A three-storey post-tensioned timber frame model was designed and dynamically tested at the structural laboratory of the University of Basilicata. The prototype model was a 3D, three-storey glulam timber frame, characterized by single bays in both directions. The frame was designed according to European code [9] for office use at first and second floors (live load of  $Q = 3$  kPa) and considering a rooftop garden load ( $Q = 2$  kPa). A scale factor of 2/3 was applied to the experimental model obtaining an inter-storey height of 2 m and a scaled footprint of 4 m x 3 m (Figure 2). Suitable scale factors were used observing mass similitude related to the Cauchy-Froude similitude laws [10]. The additional masses due to scaling of dead load and live load were made up of concrete blocks and steel hold downs. The beam-column connection (see Figure 1) was realized by a single unbounded post-tensioned steel bar (of 26.5 mm diameter) crossing the beam. Based on MMBA [11] procedure the tension loading of the steel bar was 100 kN and 50 kN for the longitudinal and transversal direction, respectively.

The three following testing configurations, with different amount of energy dissipation [8][12][13], were considered: i) bare post-tensioned frame (F) shown in Figure 3a, representing the free rocking condition with post-tensioning only without energy dissipation; ii) dissipative frame (DF), representing the bare frame (F) with additional dissipative rocking at the beam-column joints and at the column-foundation connection; and iii) braced frame (BF) shown in Figure 3b, representing the bare frame (F) with dissipative braces.

The seismic response of the frame was recorded by more than 50 acquisition channels. Different types of sensors were installed on the test frame, providing measurements of horizontal and vertical accelerations, absolute displacements, strain and force. Among various monitored parameters, the tendon's load was recorded by 6 load cells placed at the beam-column joints (see Figure 2), in both longitudinal and transversal directions of the experimental model in all configurations. For more information about the experimental model and data acquisition please refer to Di Cesare et al. [8]. In this study, seismic post-tensioning losses during shaking table tests and the long-term post-tensioning losses among the various configurations have been investigated.

### 3 POST-TENSIONING VARIATIONS

#### 3.1 Variations due to seismic motion

The experimental campaign was performed using a set of seven natural earthquake records, selected from the European strong motion database. The spectra-compatible records were defined according to the current Eurocode [9] considering a peak ground acceleration PGA of 0.44 g and medium soil class (type B) in high seismic zone. To ensure consistency with the scale of the experimental model, all input accelerations were scaled down in duration by a

factor of  $1/\sqrt{(3/2)}$ . In order to match the real acceleration inputs to the Eurocode response spectrum it was necessary to scale some earthquakes by means of an appropriate scale factor.

The reduced set of three spectra-compatible earthquakes selected in this paper and the shake table testing program of all experimental configurations are summarized in Figure 4. The intensity of the ground motion was progressively increased in acceleration for earthquake cases 1228, 196, 535 from 10% to 100% of average PGA for DF and BF configurations, in order to provide additional information regarding the frame response at varying damage levels.

Figure 4: Testing program for selected seismic inputs of the experimental model and selected seismic inputs.

During shaking table tests the tension load has been recorded and the post-tensioning variation  $\Delta F_{PT} = (F_{PT,max} - F_{PT,initial})$  for the three testing configurations (F, DF and BF) has been evaluated. The maximum and mean variation of post-tensioning force  $\Delta P_T$  are shown in Figure 5 for all configurations at increasing PGA levels. As can be observed, the introduction of the bracing system was effective in reducing the post-tensioning of over 50% than F configuration.

Figure 6 shows the time histories of the post-tensioning variation  $\Delta F_{PT}$  of the first storey beam-column connection and Figure 7 and Figure 8 show  $\Delta F_{PT}$  versus drift for the three selected seismic inputs at 25% and 75% of PGA level of all testing configurations. As can be observed at low PGA level of all seismic inputs the PT bar was slightly activated with a maximum PT variation of 12 kN in F model configuration due to the elastic response of the frame model. At PGA 75% the re-centering effect due to the post-tensioning is more evident in all configurations. It can be observed that increasing amount of energy dissipation introduced in the frame (from F to DF and to BF configurations) led to a significant reduction of drift and of post-tensioning force variation demonstrating the effectiveness of the design procedure. In all cases a complete re-centering of the connection is observed without damages on the structural elements in all configurations tested.

Seismic post-tensioning losses due to subsequent earthquakes have been also investigated, considering the complete sequence of shaking table testing at all PGA levels (from 10% to 100%). The post-tensioned bars were tensioned to the design PT force of 100 kN in the test direction only at the beginning of each test configuration (F, DF and BF model). Figure 9 shows the post-tensioning loss at the end of seismic sequence, defined as the variation between the initial and the final value of the post-tensioning force recorded within the complete set of ground motion for each testing configuration at all levels both in longitudinal and transversal direction. It results negligible for the cases of bare frame F and of braced frame BF models and slightly higher than 2% for the dissipative frame DF model along the longitudinal direction due to the strengthening effect of dissipative angles of the post-tensioned beam-column joints. Results highlight the capability of the building to withstand multiple consecutive strong earthquakes. During the experimental campaign over than 100 tests were performed for each configuration without observing any structural damage.

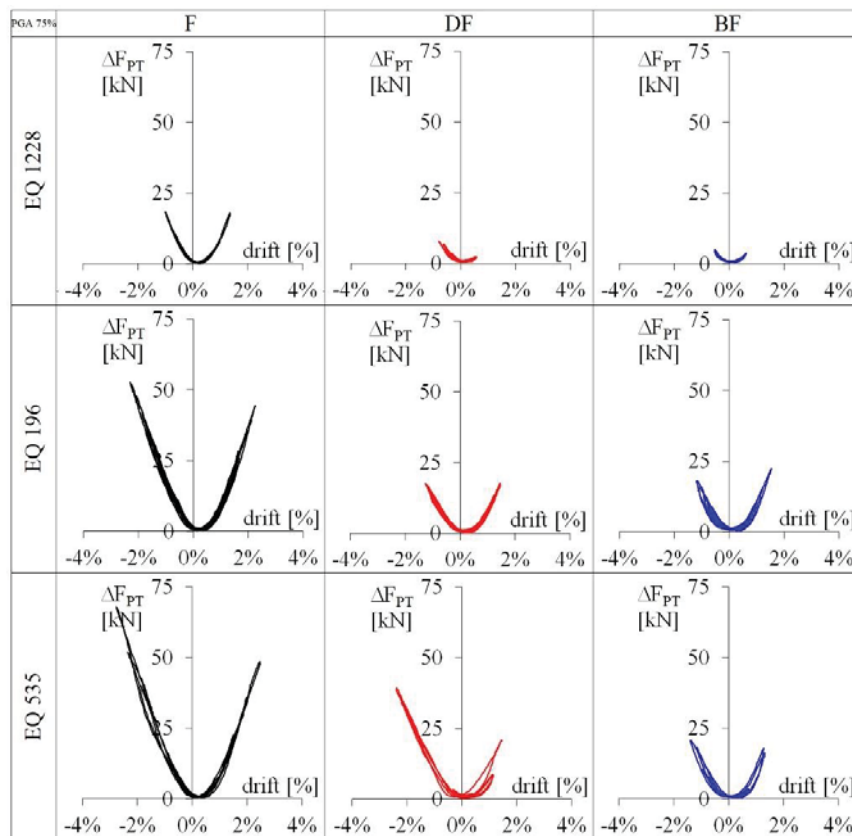

Figure 8: Post-tensioning variation versus drift for the three selected seismic inputs at 75% of PGA.

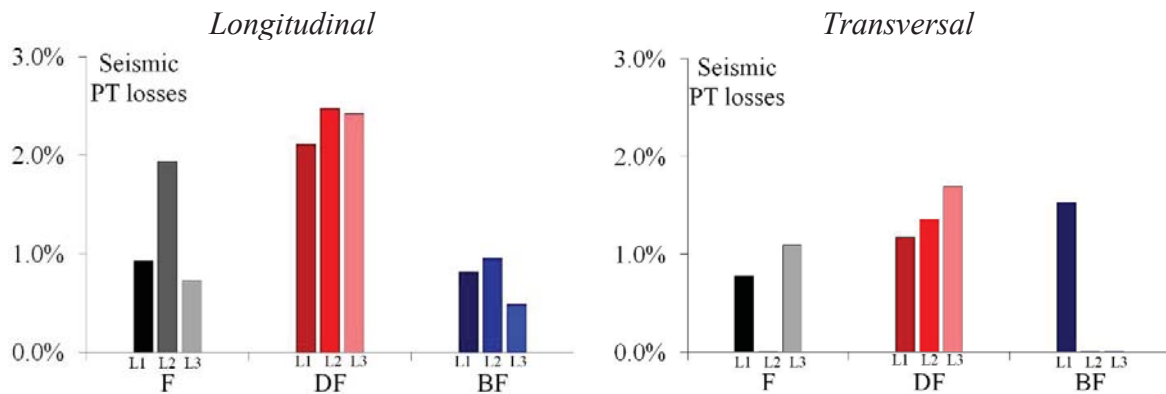

Figure 9: Seismic post-tensioning losses recorded for the three testing configurations at the three levels in longitudinal and transversal direction.

### 3.2 Variations due to long term effects

The long-term post-tensioning losses at all levels both in longitudinal and transversal direction of bare frame F and dissipative frame DF configurations are shown in Figure 10 in terms of post-tensioning force ( $F_{PT}$ ) recording over a time period of about one year after testing of F configuration and over about three years after testing of DF configuration. Percentages values of post-tensioning losses are reported in Table 1.

Figure 10. Post-tensioning losses over time for F and DF configurations at all storey in longitudinal (L) and transversal (T) directions.

Model Config.	$\Delta t$ [days]	Post tensioning losses [%]					
		Longitudinal			Transversal		
		1 <sup>st</sup> storey	2 <sup>nd</sup> storey	3 <sup>rd</sup> storey	1 <sup>st</sup> storey	2 <sup>nd</sup> storey	3 <sup>rd</sup> storey
F	321	15%	13%	13%	29%	27%	25%
DF	1101	25%	26%	22%	43%	41%	39%

Table 1. Post-tensioning losses recorded over time at all storey for the F and DF configurations.

As expected, a decreasing trend of post-tensioning force was observed in both F and DF configurations. It can be pointed out that in case of DF configuration after a period of about 2 years the post-tensioning losses stabilized at around 25% in the longitudinal direction. Highest post-tensioning losses were recorded for both F and DF in the transversal direction. Moreover, by comparing the trend of post-tensioning force recorded for F and DF specimens during the first year both in the longitudinal and transversal direction, lower post-tensioning losses were observed in the frame with dissipative rocking mechanism at the beam-column connections. During each configuration the bars were not re-tensioned over time and post-tensioning losses can be significant when the PT connection is left to transfer the post-tensioning load. However, in case of operative timber structures the effect of long-term losses can be contrasted by using disc springs designed for the initial PT force, characterized by high load capacity with a small spring deflection, and periodically monitored and/or re-tensioned.

#### **4 CONCLUSIONS**

This paper investigates on the long-term and seismic post-tensioning losses of a 3D, three storey, 2/3 scaled post-tensioned timber framed building designed and tested at the structural laboratory of Basilicata. The extensive shaking table testing campaign was performed in three different configurations, considering the bare frame with post-tensioning only, with dissipative rocking mechanisms and with dissipative bracing systems, subjected to different seismic inputs at increasing PGA levels. During each testing configuration the frame was not re-tensioned.

The results showed that during the seismic motion, the variation of post-tensioning force at due to the rocking at the beam-column joints and the gap opening reduced with the introduction of dissipative systems, in DF and BF configurations. Moreover, the post-tensioning losses recorded within the complete set of ground motions for each testing configuration at all levels both in longitudinal and transversal direction were negligible. The maximum recorded value was of about 2% in DF configuration due to the strengthening effect of dissipative angles. The long term the post-tensioning force decreased linearly in the first two 2 years, reaching a 25% of losses, after that responded almost constant.

### Abstract

*Curved Surface Slider devices have been widely used in last years for the protection of both building and structural systems. The spherical shape of the implemented sliding surfaces provide a certain recentering capability, which is generally combined to significant amount of energy dissipation, due to the frictional characteristics of the adopted sliding material. Since both behaviors act simultaneously during motion, experimental tests could return significantly high force values, especially if large bearings are considered. In some of those cases, the maximum force capacity of the testing equipment can be even overcome, and consequently experimental tests can not be performed.*

*The scope of the present work is to provide experimental evidence of the comparison between flat and curved sliding motions. Precisely, the outcomes of bi-directional tests performed on on full-scale Double Curved Surface Slider and Flat Slider devices have been analyzed. On the former typology the frictional and the recentering behaviors have been numerically decoupled, in order to compare the obtained results to the frictional response of the latter device. Results have shown a good agreement between the considered sliding motions, which seems to suggest that the experimental evaluation of flat sliding characteristics could be representative of curved sliding motions.*

**Keywords:** Curved Surface Slider, Flat slider, base isolation, Experimental campaign, friction coefficient.

---

## 1 INTRODUCTION

In last years the research about Curved Surface Slider devices has shown good performance in reducing the structural vulnerability of both buildings and bridge structures ([5] , [4] , [12] , [13] ). The overall response can be significantly mitigated, through the energy dissipation induced by the frictional behavior of the sliding motion, together with potentially low residual displacements, thanks to a properly designed recentering characteristics. In addition, the growing interest in investigating the experimental response of such devices have highlighted a number of important aspects to account for, such as some dependencies of the friction coefficient with respect to specific response parameters, in terms of sliding velocity, vertical load/contact pressure and cyclic effect ([6] , [11] ). These dependencies have been detected, by analyzing the force response of both flat and curved sliding motions, and consequently a certain correlation between these different loading conditions is expected, regardless the applied loading conditions ([7] , [9] , [2] ). From a theoretical perspective, the lateral force of a Curved slider can be computed as the summation of a recentering behavior, modeled as a linear spring with respect to displacements and a frictional response ([3] , [10] ). This relationship can be used to compare the frictional response of flat and curved sliding motions. If results between the aforementioned sliding conditions were actually comparable, testing possibility of curved devices would increase, since it would be possible to perform tests on the flat sliding material only, rather than the full curved isolator, and consequently much lower force demands could be achieved. In this work the outcomes of a wide experimental campaign on full-scale flat and curved sliders are analyzed, in terms of comparison of the resulting frictional properties. The considered dynamic tests have been performed at the Laboratory of EUCENTRE Foundation in Pavia, by adopting a special testing setup, in order to apply bidirectional motions.

## 2 TESTED DEVICES

In order to analyze the differences between flat and curved sliding motions, two individual typologies of sliding devices have been adopted. Precisely, full-scale isolators have been adopted, aiming at obtaining more realistic experimental results, as representative of the proper loading conditions of the devices ([6] ).

The former device consists of a Flat Slider, which returns the pure frictional behavior: it consists of a stainless steel flat sliding surface, which has been polished to mirror finish, by considering a roughness index  $R_a$  0.2, and a slider with a circular sliding pad. Such a device can be subjected to bidirectional displacements up to 250mm.

The latter isolator is a Double Curved Surface Slider, which represents one of the most common technology for isolation bearings. Two spherical sliding surfaces with the same curvature radius have been implemented, both polished to mirror finish in order to achieve the same roughness index of the Flat Slider: consequently, same frictional properties can be ensured; in addition, since the same radius of curvature has been designed for both the upper and the lower spherical surfaces, the global horizontal motion applied to the device can be considered as halved in two opposite sliding motions at the sliding interfaces. Within the equal sliding surfaces, a non-articulated slider is installed, which is made up of a unique steel block (material S355JR): such an element houses two circular sliding pads, having same diameter (260mm) and same material composition, aiming at considering the same contact pressure and the same frictional properties at both the sliding interfaces. Both the radii of curvature of the spherical surfaces are 1600mm each, with internal slider height of 120mm: consequently, the equivalent radius of curvature of the device is approximately equal to 3080mm.

In Figure 1 both the adopted isolation devices are shown.

Figure 1: Full-scale Flat (top) & Concave (bottom) Surface Slider devices (FS & DCSS)

Isolation devices have been equipped with an innovative sliding material, which returns a controlled frictional response. Precisely, a pigmented graded PTFE filled with carbon fibres has been considered. The chemical formulation, such a material results in a much stiffer material in comparison to ordinary PTFE compositions. For both the typologies of isolation devices, three different sliding pad sizes have been considered, as shown in Figure 2.

Figure 2: Internal sliders for Flat and Curved devices

Thanks to the adopted sliders it is possible to analyze the comparison between flat and curved sliding conditions also for different sizes of the sliding pads, which may influence the distribution of the contact stresses at each interface and, consequently, the frictional response.

### 3 BIDIRECTIONAL TESTING PROTOCOL

The testing protocol has been defined, by considering bidirectional tests, according to the cloverleaf orbit, which is ruled by the European standard code UNI:EN15129:2009 for anti-seismic devices ([1]). Tests have been carried out through the Bearing Tester System at the Laboratory of the EUCENTRE Foundation in Pavia ([8]), which provides a special equipment for the application of bidirectional horizontal motions to isolation devices. Specifically, the time series of horizontal displacement along both x and y directions for the cloverleaf orbits can be returned by the following expressions:

$$\begin{aligned} x(t) &= \frac{D_{\max}}{\sqrt{2}} \cdot \sin(4\pi ft) \cdot [\sin(2\pi ft) + \cos(2\pi ft)] \\ y(t) &= \frac{D_{\max}}{\sqrt{2}} \cdot \sin(4\pi ft) \cdot [\sin(2\pi ft) - \cos(2\pi ft)] \end{aligned} \quad (1)$$

Such displacement time series have to be applied simultaneously to the device, which is consequently subjected to a bidirectional motion.

Figure 3: Cloverleaf bidirectional orbit

The aforementioned analytical definition of the displacement input leads to the following expression of the peak vectorial velocity of the test.

$$V_{\max} = 4 \cdot \pi \cdot f \cdot D_{\max} \quad (2)$$

In order to better characterize the frictional properties of all the investigated devices, by ensuring a constant value of vectorial sliding velocity, input signals for bidirectional tests have been modified. Precisely, according to the aforementioned analytical definition of motion, the tangent velocity modulus varies between 50% and 100% of the peak value of the test, variations which may induce unexpected discrepancies in the overall frictional behavior of the considered device. Thus, a special resampling procedure has been applied to all tests, in order to obtain a constant modulus of the tangent velocity for the whole duration of motion. In Fig-

Figure 4 a comparison of the input signals for ordinary and CTV (Constant Tangent Velocity) orbits is provided.

Figure 4: Comparison between ordinary and CTV bidirectional orbits

The aim of the present research work is to directly compare the frictional response of both flat and curved sliding motions, by adopting different diameters of the implemented sliding pads, under bidirectional motions. In order to obtain to apply to the flat slider the effective motion of a single sliding interface of the curved isolator, the geometrical characteristics of the adopted spherical surfaces and the internal slider have been studied. Precisely, since the Curved Slider has the same radius of curvature for both the sliding surfaces, each sliding interface of the internal slider is subjected to 50% of the global displacement applied to the curved device; consequently, the velocity at the sliding interface is also halved. Hence, the testing protocol of the Flat Slider (FS) is obtained by halving peak values of both maximum displacement and velocity of the curved device.

In Table 1 the testing protocol for all the devices is summarized.

Table 1. Bidirectional testing protocol for DCSS devices

Test #	Trajectory	Maximum Displacement [mm]			$V_{\max}$ [mm/s]	P [MPa]
		$\Phi 160$	$\Phi 260$	$\Phi 360$		
1	Cloverleaf CTV (2 repetitions)	150	200	120	20	15
2					80	
3					300	
4	Cloverleaf CTV (2 repetitions)	150	200	90	20	33
5					80	
6					300	
7	Cloverleaf CTV (2 repetitions)	150	200	-	20	45
8					80	
9					300	

The vertical load of each test has been computed, by applying 15MPa, 33MPa and 45MPa contact pressures for each sliding pad diameter, and by considering two repetitions of bidirectional CTV cloverleaf orbit for all tests. It has to be noted that 45MPa pressure level has not been applied to the 360mm sliding pad, due to the high resulting vertical load value.

#### 4 DEFINITION OF THE HYBRID FORCE RESPONSE

The force response of a Concave Surface Slider (CSS) device is generally computed as the summation of the restoring force, provided by the stepwise projection of the applied vertical load along the tangent line to the sliding surface, and the curved frictional force, originated at the sliding interfaces. Thus, in order to compare the force response of the flat and the curved sliders, a hybrid force signal has been computed for both x and y directions, in terms of summation of an experimental flat frictional force, provided by tests carried out on the Flat Slider, and a numerical recenetring force, modeled as a linear spring with respect to displacements along x and y directions.

$$F_{Hybrid} = F_{f-Flat} + F_{rec-num} = F_{f-Flat} + \frac{W}{R_{eq}} \begin{bmatrix} x \\ y \end{bmatrix} \quad (3)$$

The obtained hybrid forces can be directly compared to the force response of the curved device, and resulting frictional properties can be studied. To this aim, the same diameter of the implemented sliding pads for both the tested devices has been considered, and a proper scaled flat testing protocol has been defined, in order to apply same loading conditions to all the sliding interfaces.

#### 5 AVERAGE FRICTION COEFFICIENT PER CYCLE

The cyclic behavior of the frictional response has been studied in terms of decay of the friction coefficient value, by applying an ad hoc analytical definition of the Average Friction Coefficient per cycle, comparable to the one ruled by the code UNI:EN15129:2009. In order

to do so, a proper “bi-directional cycle” has to be defined for the adopted cloverleaf orbit, similarly to what is considered when unidirectional motions are applied. Under radial tests, sinusoidal waveforms are applied, and consequently the device within a single cycle has to reach the maximum and the minimum displacements respectively starting from the centred position (the maximum value of the displacement is reached twice along two opposite directions). Consequently, if two lobes of the cloverleaf trajectory are considered, the maximum vectorial displacement is reached twice along two different (and orthogonal) directions as well. Thus, a set of two lobes of the bidirectional cloverleaf orbit can be fairly considered as a bidirectional cycle, as shown in Figure 5.

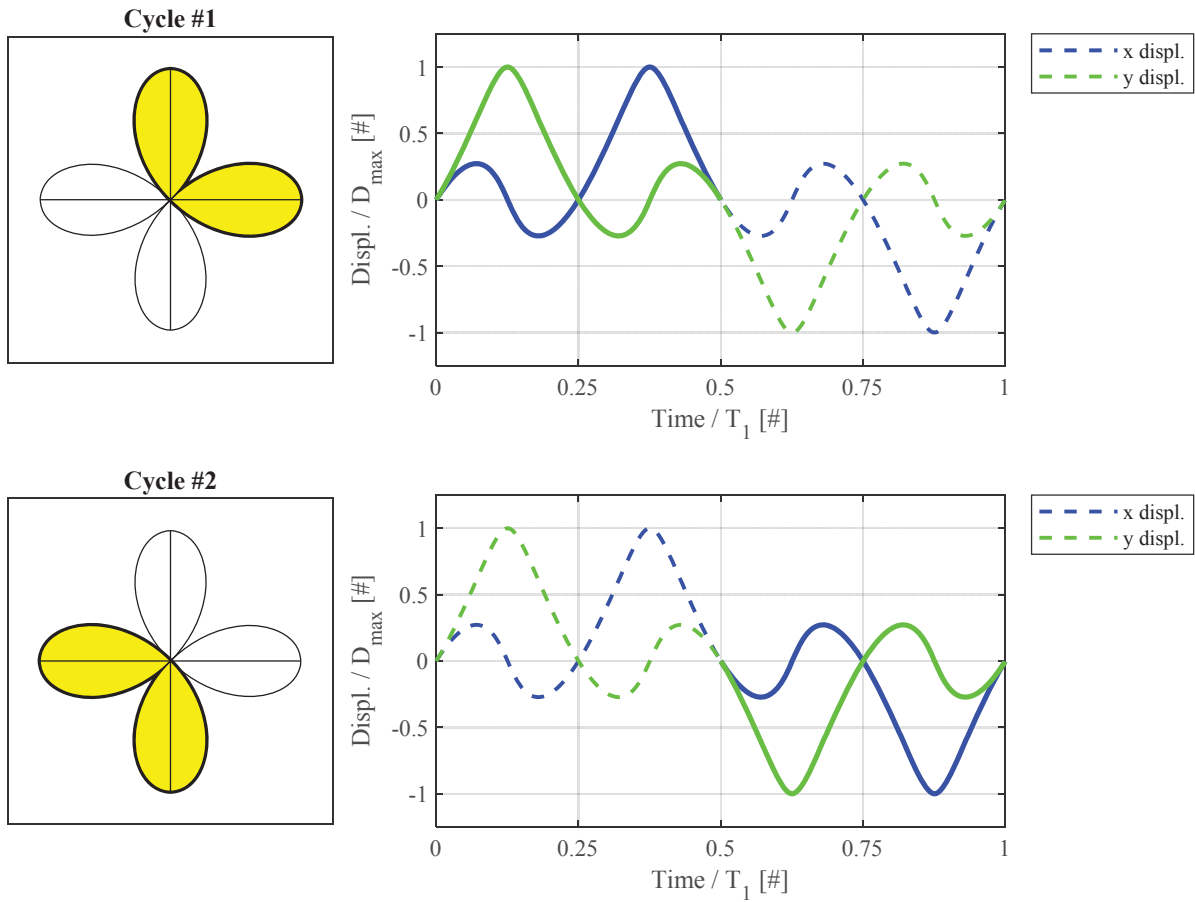

Figure 5: Definition of the bidirectional cycle

Thanks to this definition of the bidirectional cycle, for each test of the testing protocol of all devices four individual values of average friction coefficient per cycle can be computed, since the cloverleaf orbit has been repeated twice (8 lobes). The numerical value of the average friction coefficient per cycle can be computed, as a function of the Energy Dissipated per Cycle (EDC) and the product between the applied vertical load  $W$  and the total length of the bidirectional travelled path along two lobes ( $4,844 D_{max}$ ).

$$\mu_{EDC} = \frac{EDC}{4,844 D_{max} W} \quad (4)$$

The EDC value can be computed through the evaluation of the total work, in terms of integral of the scalar product between the force and the differential displacement vectors.

$$EDC = \int \vec{F} \cdot d\vec{s} \quad (5)$$

The computed average friction coefficient per cycle has to be referred to the dissipated energy value which occurs at half cycle point, which corresponds to the zero displacement point (undeformed configuration), between the achievement of the maximum displacement along the orthogonal directions (i.e. at the end of the first lobe of the bidirectional cycle).

## 6 EXPERIMENTAL RESULTS

In Figure 6, Figure 7 and Figure 8 results are shown for all the velocity levels, with a contact pressure equal to 15MPa, 33MPa and 45MPa respectively.

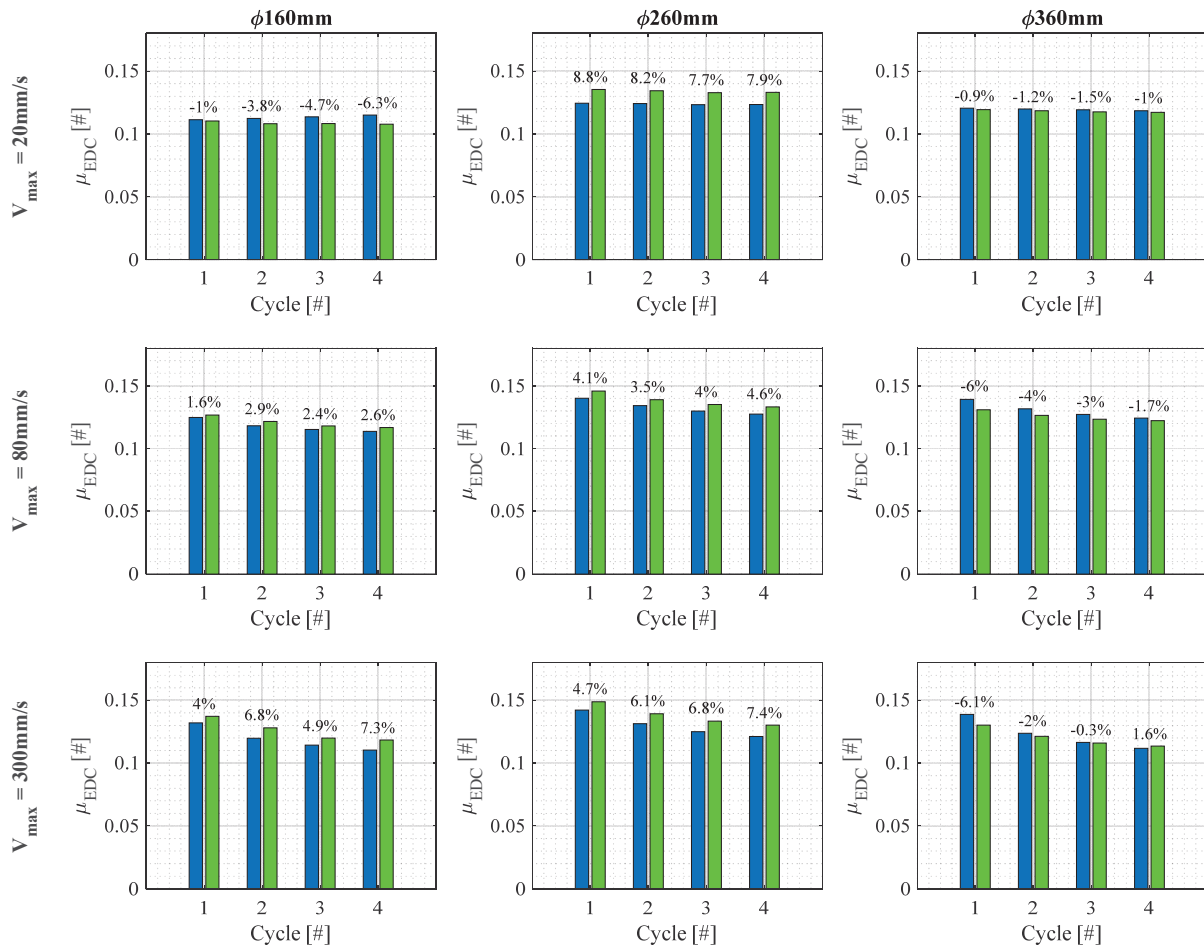

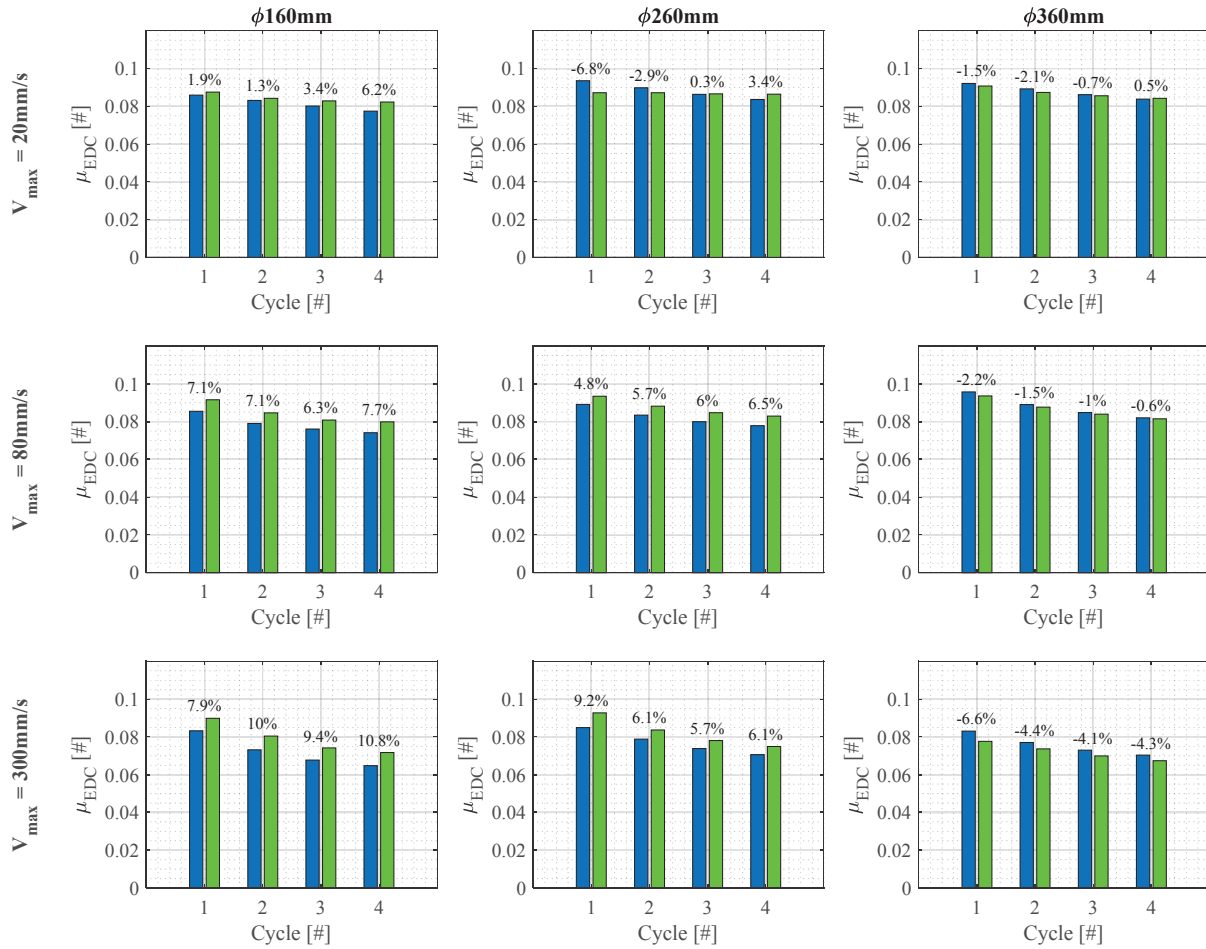

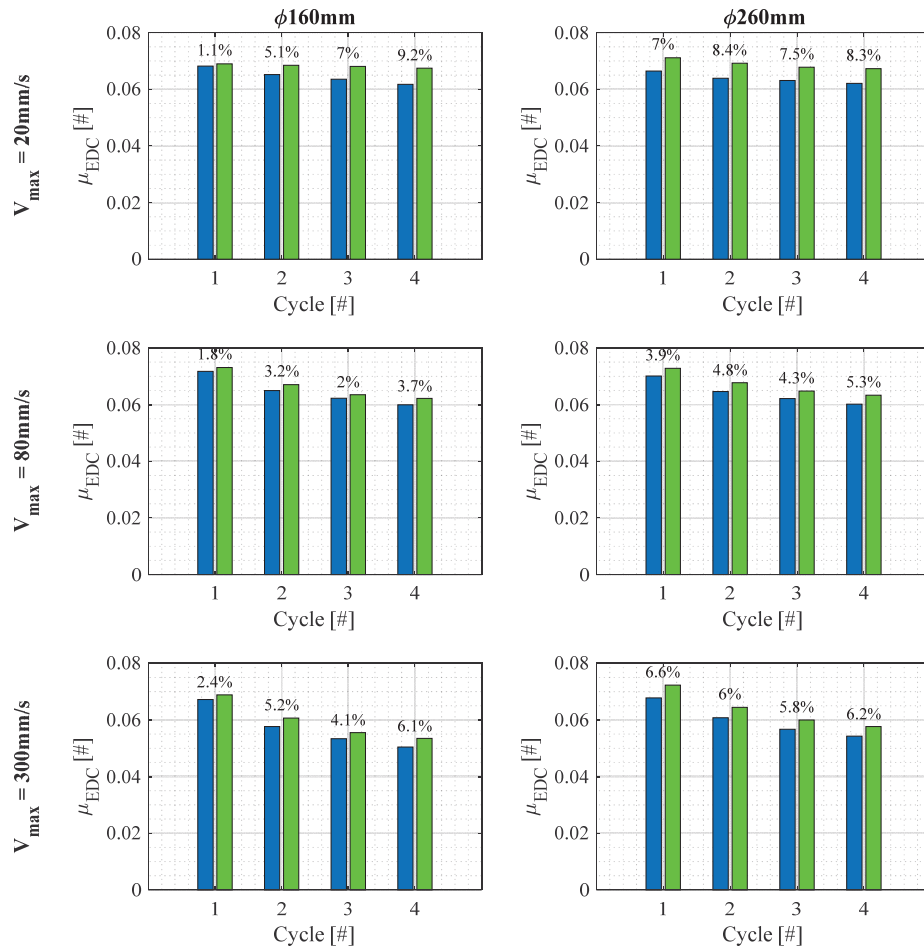

Figure 6: Average friction coefficient per cycle for **Curved** and **Flat** sliders,  $P = 15\text{MPa}$ .

 Figure 7: Average friction coefficient per cycle for **Curved** and **Flat** sliders,  $P = 33\text{MPa}$ .

Results are presented as values of average friction coefficient per each applied bidirectional cycle, which means four cycles for all the tests. More specifically, values have been computed, by considering the outcomes of tests performed on the Double Curved Surface Slider devices and the hybrid lateral response, computed as a combination of a numerical restoring force and the experimental flat frictional force. For the evaluation of the hybrid frictional characteristics, the displacement time series has been doubled, in order to consider the proper analogy with respect to the curved device. Results show a very good agreement between the frictional responses of the DCSS device and hybrid force related to the flat slider. Precisely, it can be assessed that for small-to-medium diameters of the sliding pad (160mm and 260mm) the hybrid friction coefficient is generally higher than the corresponding value related to the curved device, whereas for large diameters (360mm) flat motions lead to lower friction coefficient values, in comparison to curved isolators, especially for high velocity. In all figures variation values are reported, in terms of variation of the friction coefficient returned by the hybrid response, with respect to the value related to the curved device. As can be noted, such variation values are less than 10%, which highlight that the proposed method for frictional characterization provides a very good estimate of the real properties of the DCSS isolator.

 Figure 8: Average friction coefficient per cycle for **Curved** and **Flat** sliders,  $P = 45\text{MPa}$ .

Another aspect which can be noticed by analyzing graphical results is related to the frictional decay and the actual numerical values of the average friction coefficient per cycle. Precisely, it can be assessed that numerical values returned by the different sliding pad diameters are comparable, and approximately the same decay trend can be detected for all the velocity and contact pressure levels. This is a very important experimental evidence, which seems to prove that different diameters of the sliding pad actually lead to the same frictional properties, characterized by the same cyclic effect, if the proper motion is applied.

## 7 CONCLUSIONS

The presented experimental research provides the comparison between the frictional response returned by both flat and curved sliding motions. A large number of bidirectional dynamic tests have been performed at the Laboratory of EUCENTRE Foundation in Italy, by applying different loading conditions (i.e. contact pressure and sliding velocity) to ad hoc designed and realized full-scale devices, in order to provide results more comparable to applications commonly developed in the real practice. Precisely, Flat Sliders (FS) and Double Curved Surface Sliders (DCSS) have been adopted, by considering three individual sliding pad diameters. The testing program of the flat devices has been computed, by halving the peak displacement and velocity of the tests performed on the curved isolators, since both the

spherical sliding surfaces have the same radius of curvature, and consequently the same sliding motion is originated at each sliding interface. Both the typologies of tested devices have been equipped with an innovative sliding material, which consists of a graded PTFE filled with carbon fibres. In order to carry out bidirectional tests, the cloverleaf orbit has been adopted, as ruled by the European standard code for anti-seismic devices UNI:EN15129:2009; in addition, displacement time series along both  $x$  and  $y$  directions have been resampled, in order to obtain a constant tangent velocity modulus for the whole duration of all tests. Average friction coefficient per cycle values have been computed, according to a proper definition of bidirectional cycle for the adopted orbit, and Flat and Curved frictional properties have been compared, by means of a hybrid response: such a force response can be computed as the summation between the experimental frictional force of the Flat Slider device and a numerical recentering force, modeled as a linear spring with respect to displacements (displacement time series have been doubled, in order to consider the actual motion of the curved devices). Results have been analyzed, in terms of average friction coefficient per each bidirectional cycle (four full cycles for each tests).

According to the presented results, it can be assessed that:

- The proposed hybrid response, computed as a function of the flat slider outcomes, leads to a very good estimate of the frictional properties of the corresponding curved device;
- The variation between the hybrid and the curved responses is bounded between  $\pm 10\%$ , and in most of cases the average friction coefficient per cycle achieves higher values, when the hybrid force is adopted, especially for small-to-medium diameters of the sliding pads, and for high velocities;
- Different sliding pad diameters seems to lead to approximately same frictional properties, from both numerical values and cyclic effects (decay trend of the friction coefficient) points of view.

The obtained results look extremely promising, since curved sliding motions for the considered devices can be actually represented by equivalent flat responses, with small variations of the correspondent frictional behavior. The importance of such a conclusion can be noticed from both an economic and a technical standpoints: if the recentering contribution can be actually numerically modeled and the frictional response can be tested by considering an equivalent flat device, the behavior of Curved Surface Slider (CSS) devices can be easily captured by the definition of the hybrid response, and consequently large devices can be fully characterized, even though large force demands are experienced. Consequently, if the testing equipment is able to perform tests on the flat slider, the response of the curved isolator can still be obtained; nonetheless, if the capacity of the testing equipment is not enough to perform tests on the full-scale flat slider, a scaled sliding pad can be considered. Such results may need further experimental investigations, by analyzing different diameters of the sliders, rather than other sliding materials, commonly adopted in real practice applications.

### Abstract

*This paper deals with the new Research Centre designed for the University of Camerino and entirely financed by the national Civil Protection Department (DPC), following the seismic events in Central Italy in 2016. The building consists of a base-isolated steel braced super-structure and r.c. sub-structures able to adapt to the complex morphology of the area. In particular, the first part of the paper illustrates the design choices made to achieve a high level of resilience and robustness of the building, i.e. to limit damage to structural and non-structural components and equipment under moderate and design seismic actions and to avoid disproportionate consequences in the event of extreme actions, larger than the design ones. The second part of the paper is focused on static and dynamic tests performed during the construction phase of the building. At the end of the structural system construction (including sub-structures, the isolation system composed by elastomeric bearings and flat sliders and the steel super-structure), the building has been tested by means of static and dynamic (snap-back) in-field tests up to a displacement of the isolation system of 280mm and 220mm, respectively. Displacements have been imposed by means of a properly designed testing mechanism and different measure instruments have been placed in the building to register the structural response.*

**Keywords:** Hybrid base-isolation system; elastomeric bearings; seismic reliability; seismic robustness; in-field tests; in-field snap-back tests.

## 1 INTRODUCTION

The new Research Centre of the University of Camerino, called Chemistry Interdisciplinary Project (*CHIP*), is a strategic building intended for high-risk activities of the chemistry and physics laboratories, whose construction started after the 2016 seismic sequences in the Central Italy [1]. The building has been entirely financed by the national Civil Protection Department (*DPC*) and it will be also used as coordination center for civil protection post-earthquake activities in the case of possible future seismic events. Due to its use destinations, the building has been conceived by adopting a structural solution able to guarantee a high level of safety, especially with regard to seismic actions, and, at the same time, the speed of execution (and possible dismantling). To this purpose a base-isolated steel braced structure with pinned joints has been conceived with r.c. sub-structures able to adapt to the complex morphology of the area. In particular, a hybrid isolation system has been adopted, comprising High Damping Rubber Bearings (*HDRBs*) and low-friction Flat Sliding Bearings (*FSBs*) able to provide a high period of isolation and a moderate damping [2]. This solution is suitable in providing both resilience and robustness to the building. In fact, the hazard of the site does not lead to excessive displacements for strong earthquakes, which can be faced with a moderate damping. Moreover, for lower displacements the stiffness and damping of this kind of bearings only slightly increase, resulting in low accelerations of the super-structures and thus no damage (and downtime) of non-structural elements and interior contents. In addition, two complementary strategies have been adopted to also ensure adequate structural robustness against extreme actions, larger than the design ones. The first consists of a safety margin adopted for the displacement capacity of both the devices composing the isolation system and the seismic gaps on the upstream side of the building. For both of them a capacity limit greater than the maximum design displacement at the Collapse Limit State (*CLS*, characterized by a return period of  $R_P = 950$  years) has been required to avoid anomalous behaviours, such as the exit of the sliders out of the sliding surface or the impact of the building with neighbouring structures. The second strategy consists of adopting a steel super-structure equipped with elasto-plastic braces characterized by a proper over-strength, which is important in the case of extreme horizontal actions causing an increase in the stiffness of the *HDR* bearings (due to their hardening behaviour for large shear strains) or the closure of the gaps. Moreover, the robustness under exceptional scenario (such as fire events or explosions) leading to the loss of vertical bearing of isolators is ensured by adopting safety supports around the devices. Finally, with the aim of increasing also the reliability of the building, an in-field experimental campaign has been planned during the design phase of the building. Many similar tests have been carried out in the past on isolated structure in Italy [3][4][5][6]. Some of them adopted a releasing device based on a quadrilateral articulated strut structure with a central fuse [7][8][9], as also used in this work.

In this paper a description of the building is first presented, successively the main design aspects of the base isolation hybrid system and of the in-field tests (testing device as well as reaction structure for the contrast) are illustrated in detail. The last part of the paper describes the static and dynamic in-field tests carried out at the end of the structural system construction (including sub-structures, the isolation system and the steel super-structure). Preliminary results are illustrated even in the light of tests carried out during the bearings production. For the interested reader a video description of the video can be found in [10].

## 2 BUILDING DESCRIPTION AND DESIGN

The upper part of the building (super-structure) is made of steel elements and it is developed by assuming a 7.2 m x 7.2 m modular system, for a total of 7 modules along each direction, plus a cantilever zone, which spans 1.9 m, along the entire perimeter of the building (Figure 1).

The steel elements have been optimized in terms of dimensions and connection systems based on the single module, resulting in a significant saving on materials and an important reduction in construction time. The isolation system has been placed at the horizontal level above the r.c. elements of the sub-structure; this latter has been designed to adapt itself to the ground profile characterized by a remarkable slope. The characteristics of the soil and the variability of the thickness of the deformable layer led to the adoption of deep foundations (Figure 1).

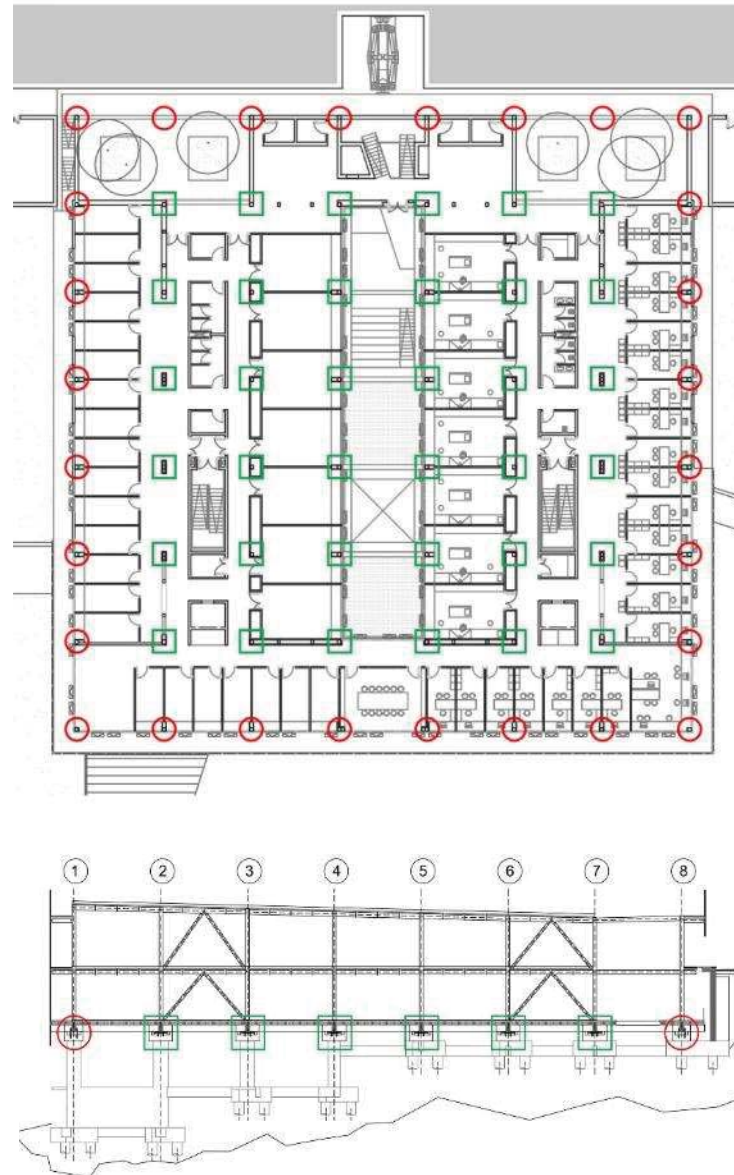

Figure 1: Plan view and longitudinal section of the building (red circles represent *HDRBs* and green squares represent *FSBs*).

## 2.1 Design of the base-isolated building

The isolation system has been designed considering a target period of  $T_{is} = 3.5$  s at the design intensity earthquake (having an exceedance probability of 2.5% in 50 years), to be able to guarantee a significant reduction of the actions transferred to the super-structure in the case of a seismic event. The solution adopted to achieve the desired period involves the use of a hybrid isolation system with *HDRBs* arranged on the perimeter, in order to maximize torsional stiffness,

and *FSBs* in the central part to support higher vertical loads. *HDRBs* commonly used in Italy have a damping ratio ranging from 10% to 15% [11]. However, for the design of the isolation system, the lower limit of 10% of damping and a shear stiffness equal to 0.4 MPa (soft rubber) were assumed in the design phase, in order to deal with different producers. For what concerns the *FSBs*, a dynamic friction coefficient less than 1% was required, to reduce the activation force and possible activation of superior modes and consequently higher accelerations [2]. In a preliminary phase, the bearings were dimensioned by assuming rigid both the super-structure and the sub-structures to obtain a 1-DOF (single degree of freedom system) and by neglecting the slider friction. Thus, the elastic response spectra have been used, reduced for all the periods in the range  $T \geq 0.8T_{is}$  by the equivalent damping of the *HDRBs*. Figure 2 shows the elastic displacement and pseudo-acceleration spectra for the considered site (Camerino, soil type B) at the different limit states, that is the Operational Limit State (*OLS*), the Damage Limit State (*DLS*), the Ultimate Limit State (*ULS*) and the Collapse Limit State (*CLS*), characterized by return periods respectively equal to  $R_P = 60$  years,  $R_P = 100$  years,  $R_P = 950$  years and  $R_P = 1950$  years, according to the national seismic code NTC 2018 [12] for the use class IV. The design was carried out by deriving the maximum displacement of the isolators from the displacement spectrum at the *CLS* corresponding to the isolation period of 3.5 s, which is about 0.27 m. An average design shear strain equal to 1.5 is assumed, ensuring a significant safety margin against possible shear failure, even in the presence of accidental torsional effects, because significantly lower than the maximum value allowed by the European standard on anti-seismic devices EN15129 [13], which establishes a value equal to 2.5.

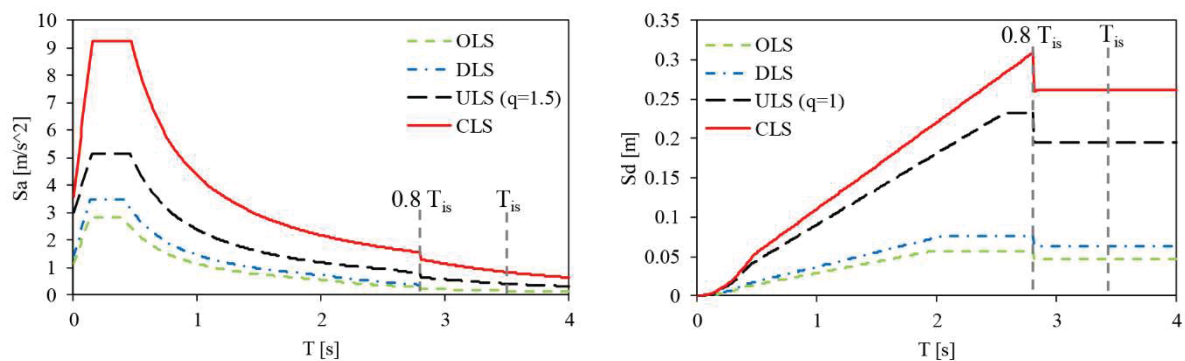

Figure 2: Elastic pseudo-acceleration and displacement spectra at the different limit states

Based on the total rubber area obtained and on the devices generally available on the national market, the following types of devices have been chosen: (i) elastomeric isolators with a diameter of 600 mm, total height of rubber 184 mm, with horizontal rigidity 0.62 kN/mm and maximum displacement 350 mm, (ii) sliding supports with a maximum displacement of 400 mm and friction coefficient lower than 1%. The final choice of devices led to a slightly higher isolation period equal to  $T_{is} = 3.60$  s. It should be noted that the displacement capacity of both the devices is larger than the maximum displacement at the *CLS* accounting also for torsional effects, which can be estimated as  $270 \cdot 1.2 = 324$  mm. As already highlighted in the introduction, larger safety assumption guarantees the absence of anomalous behaviours due, for example, to the exit of the sliders for actions greater than those considered in the design. The higher value chosen for the *FSBs* with respect to the *HDRBs* is related to the lower robustness of the former because displacements higher than the sliding surface dimension suddenly lead to a loss of bearing capacity. On the contrary, rubber isolators can usually sustain displacements larger than their nominal capacity without a significant loss of performance. An adequate dimension (350

During the building construction, in-field dynamic “snap-back” test and static tests have been performed in order to verify the actual behaviour and the characteristic of the isolation system. With this purpose, the design of the releasing device and relevant contrasting structures has been conducted during the design phase of the building. In particular, a “reaction box” made by r.c. walls and founded on piles has been arranged in the upstream part of the building to place the releasing device, as depicted in Figure 1. Figure 3 reports a plan view and a longitudinal cross section of the “reaction box” and of the releasing device. It is worth to note that the estimated maximum reaction force is about 5000 kN and all the nine piles of the box base slab collaborate in contrasting it. Moreover, the reinforcements of the building slab, where the releasing device is attached, has been properly designed and detailed according to a strut-and-tie tall beam model (Figure 4 and Figure 5 a). Similarly, proper steel reinforcement bars have been located in the r.c. walls, especially near the location of the hydraulic jacks in order to avoid local punching shear mechanism (Figure 5 b).

Figure 4: Reinforcement details of the tall beam on the building side (a) and strut-and-tie main mechanism (strut=grey zones, tie=red solid lines, nodes=dark grey zones) (b).

Figure 5: Reinforcement details of the building tall beam (a) and the reaction walls (b).

The tests are carried out using two hydraulic jacks (a maximum force of 5000 kN each and a maximum stroke of 300 mm) in series with the releasing device and two load cells on the opposite side (Figure 6 a). This latter is conceptually a quadrilateral articulated steel strut blocked by the central tie and supported by steel wheels on rails to ensure the longitudinal displacement with the lowest friction force. A fuse element made of high strength turned rod (Figure 6 b) is lodged in the middle of the tie element. The strut angle respect to the pushing direction defines the ratio between the pushing force and the tension force applied to the tie. The turning geometry and the low plastic deformation of high strength steel used for the fuse ensure a brittle rupture of the rod and a high accuracy of the release force. A friction dissipative device (Figure 6 c), similar to the ones used for falling rock protection barrier, have been installed in parallel with the tie element.

Figure 6: Releasing device equipped with hydraulic jacks and load cells (a) and high strength turned rod fuse after the rupture (b), after the rupture and friction dissipative device (c).

After the fuse rupture, the elastic energy stored in the device is partially dissipated by the friction dissipative device (Figure 6 c), avoiding damages to both the cylindrical articulations and the strut elements. The dissipating mechanism is based on a friction clamp applying a calibrated force (controlled by belleville washers) to the looped cable [14]. The loop ensures an end-stroke of the rope sliding. Finally, to further secure the cell loads from possible impacts during the release phase, the releasing device was anchored on the building side using ratchet belts. It is worth to note that both the device mass and the device friction force are negligible with respect to the building mass and response.

### 3 STATIC AND DYNAMIC IN-FIELD TESTS

The isolation system of the CHIP building has been tested during the construction phase, when the structures were completed and no partition, nor external walls, neither equipment were installed. In particular, a series of Dynamic Snap-Back (*DSB*) tests and Quasi Static (*QS*) tests have been performed, during two different days (3<sup>rd</sup> and 6<sup>th</sup> July 2020). The equipment used to move the building during the *QS* tests and the first part of the *DSB* tests has been described in section 2.2, while some measurement instrumentations are illustrated in Figure 7.

Figure 7: Sensors for recording vertical (a) and horizontal (b) displacements.

The sequence of the tests, the maximum applied displacements and thrust forces are reported in Table 1. Residual displacements at long time (immediately before the subsequent test) are also reported in the last column of the table. The last test (*QS7*), in which the maximum displacement has been imposed, showed the largest residual drift (31.4 mm) but a large part of it was recovered after few days from the test (final residual displacement equal to 25 mm).

Test	Date	max displacement [mm]	max Force [kN]	Residual displacement [mm]
<i>Pre-test1</i>	3 <sup>rd</sup> July	0.0	518	0.0
<i>DSB2</i>	3 <sup>rd</sup> July	177.3	2729	15.2
<i>QS3</i>	3 <sup>rd</sup> July	232.4	3206	22.1
<i>DSB4</i>	6 <sup>th</sup> July	109.4	1756	22.1
<i>DSB5</i>	6 <sup>th</sup> July	226.9	3122	22.0
<i>DSB6</i>	6 <sup>th</sup> July	121.8	1786	22.4
<i>QS7</i>	6 <sup>th</sup> July	284.6	3834	31.4→25

Table 1: Tests sequence

Figure 8 (a) reports results in terms of response curves, i.e. loading force-displacement curves of some *DSBs* and the loading and unloading force-displacement curves of the two *QS*

tests, showing some characteristic behaviours of hybrid isolation systems composed by *HDRBs* and *FSBs*. The first one is the breakaway friction force of the system. During *DSB2* test the structure is moved for the first time from its initial position and starts to move after reaching a force of 700 kN, which is higher than the breakaway friction force observed during all the subsequent tests. The reason is that the trajectory followed by all the tests is almost the same, thus the lubrication of the sliding surfaces increases at each test. Furthermore, from the unloading branch, the dynamic friction force can be estimated since the vertical drop at the maximum force is theoretically 2 times this force. The obtained values, highlighted in Figure 8 (a), are approximately equal to 400 kN for both the *QS* tests, thus the dynamic friction force is estimated to be nearly 200 kN, which is significantly lower than static friction force. Both the reduction of the friction due to repeated cycles and the difference between static and dynamic friction are phenomena already known in specific technical literature [15]. However, it can be noted that after the tests the building does not restore its initial position, thus the initial force measured to start the movement is not only related to the friction of *FSBs* but also to the residual force of *HDRBs*. From Figure 8 (a) it is clear that after having performed the *DSB2* test, the succeeding *QS3* test starts in a displaced configuration equal to 15 mm and equal to 23 mm for all the following tests, resulting in a horizontal shifting of the responses.

Another characteristic aspect that can be observed from the tests deals with the viscous behaviour of *HDRBs* (i.e. the influence of the displacement rate on the response). To better explain this point the response curves of Figure 8 (a), once deduced the dynamic friction force previously estimated and scaled with respect to a single *HDRB*, have been compared in Figure 8 (b) with the response curves of two type tests, carried out according to [13] before the bearings production. Specifically, such tests are the Horizontal Cyclic test at 150% shear deformation at third cycle (*HC* in Figure 8 b) and One Side Ramp test (*OSR* in Figure 8 b). It can be observed that the *HC* test (performed at 0.5 Hz, with a mean speed of 550 mm/s) is stiffer and more dissipative than all the other tests, which have been carried out with a significantly lower displacement rate (about 5 mm/s the *OSR* type test and 0.2 mm/s the load branch of in-field *QS* tests). A further remark involves the in-field *QS* tests, whose loading branch is very close to the *OSR* test, even though the speed is different. On the contrary, the unloading branches are significantly different due to the different unloading modalities, resulting in a lower energy dissipation and a higher recentring capacity of the *QS* in-field tests. For what concerns the loading phase of the *DSB2* in-field test, the response significantly differs from the other tests because it is affected by the first breakaway friction force and by the first cycle effect of the “virgin” rubber, i.e. the first time that all the *HDRBs* reach this level of strain [16][17].

Figure 8: Force-displacement curves of the in-field tests (a) and their comparison with type tests with reference to a single *HDRB* (b).

Finally, Figure 9 summarizes the displacement time-histories observed during the *DSB* tests. It is worth to note that the isolation period, ranging between 2.5 s and 3.12 s, is lower than the design period due to the lower mass of the isolated building during the tests with respect to the design one. Furthermore, it can be observed that the free vibration of the building oscillates between a non-zero displacement configuration, but a slow recentring displacement can be recognized by looking at the response after 4 s from the release. This confirms the importance of the viscous component of *HDRBs* response, which leads to a final residual displacement of around 22-25 mm (see Table 1).

Figure 9: Displacements time-histories of in-field *DSB* tests.

#### 4 CONCLUSIONS

This paper describes the isolated-building of the new Research Centre of the Camerino University, called *CHIP* (Chemistry Interdisciplinary Project), with particular focus on dynamic and static in-field tests carried out during the building construction to characterize the isolation system response. The design of the in-field experiment campaign has been developed in parallel with the design of the building. In particular, a quadrilateral articulated steel strut element has been designed and used as releasing device, furthermore a reaction box has been designed close to the building and properly dimensioned. A pair of hydraulic jacks, whose force has been monitored through load cells, has been used for the pushing phase, while the displacements of the isolation system has been recorded thanks to horizontal and vertical transducers. Preliminary results, in terms of force-displacement response curves of quasi-static tests and displacement time-histories of dynamic snap-back tests have been showed and discussed. By analysing the force-displacement response curves of the quasi-static tests, both the static and dynamic friction force of *FSBs* has been estimated. The response of *HDRBs* has been also identified and compared with type tests carried on single bearing devices. Finally, the displacement time-histories of the snap-back tests have been analysed by estimating the isolation period range and the recentring capacity of the isolation system.

### Abstract

*In this paper, the change in response parameters of a seismically isolated bridge, namely maximum isolator displacement (MID) and shear force (MSF), is studied when the ambient temperatures drops to (-30°C) from 20°C. Isolation system of the analyzed bridge is assumed to be composed of lead rubber bearings (LRBs). First, the LRB was subjected to cyclic loading after a conditioning period of 24 hours at both temperatures. Test results were used to validate the success of analytical model used to idealize the deteriorating hysteretic behavior of the LRB. Then, verified analytical representation of LRB was utilized in nonlinear response history analyses in order to measure the variation in MID and MSF in the bridge model under the effect of bidirectional seismic excitations at 20°C and -30°C. Two distinct group of ground motions, that constitute characteristics of both near-field and large-magnitude-small-distance records, were used in the analyses. Results showed that MIDs obtained for LRB properties of 20°C are about 20% larger than the ones obtained for -30°C, in an average sense. Furthermore, average MSF obtained for near-field ground motions at 20°C and -30°C are identical. However, for large-magnitude-small-distance ground motions, MSF of -30°C is almost 25% larger than that of 20°C.*

## 1 INTRODUCTION

Seismic isolation is an earthquake protection system which is used for new and retrofit construction in many countries such as Japan, Italy, United State and Turkey. Its low horizontal stiffness enables the natural period of the structure lengthening, hence, in case of maximum earthquake shaking isolation systems are reduce the force demands and superstructure remain elastic behavior. Among broad classes of seismic isolation systems, lead rubber bearing (LRB) is the most popular used seismic isolator type. In these units, rubber layers reinforced by steel plates and a lead core placed at the center passes through the height of the bearing. The use of steel plates responsible for reducing the bulge and increasing the vertical stiffness of the bearing whereas lead core supplies the required strength in horizontal direction.

The usage area of LRB has been extensively increase around the world since it was invented, such as bridge, hospital, residential building, data centers. In parallel, several research has been conducted to understand the change in mechanical properties of LRB isolators, namely post yield stiffness and characteristic strength, under the effect of different parameters [1-7]. One of these parameters is the change in ambient temperature in which either affects rigidity of rubber [8-14] or needs to modify of LRB properties at low temperatures [15-17] under the effect of cyclic loading. In particular, Hasegawa et al. [15] tested a LRB which is 250 mm in diameter with a lead core diameter of 38 mm. Displacement controlled LRB tests were conducted at temperatures of 40, 20, 0 and -20°C for a shear strain of 100% at 0.3 Hz. Similarly, Constantinou et al. [4] conducted tests with an LRB having rubber and lead core diameters of 381 mm and 70 mm, respectively. On the other hand, rather than displacement-controlled test results, seismic performance of bridges, isolated by LRBs, under the effects of both ground motion excitations and low temperature have also been investigated. For instance, Billah and Todorov [18] investigated the seismic response of an LRB isolated bridge in case of subfreezing temperature. Authors performed nonlinear response history analyses (NRHA) using a bridge model subjected to different ground motions representative of earthquakes in Eastern Canada. In their study, LRBs were modeled with two different non-deteriorating bilinear force-displacement curves to idealize hysteretic behavior of LRBs at “summer” (25°C) and “winter” (-30°C) with properties provided by manufacturer. Another study that has focused on seismic response of LRB isolated bridge under low temperature was conducted by Deng et al. [19]. Similarly, in the analytical model, they used a non-deteriorating hysteretic representation for LRBs where stiffness and strength of LRB was modified in accordance with an empirical formulation. LRB properties used in the analyses were computed for temperatures changing from -30°C to 40°C. However, it is to be mentioned that both Billah and Todorov [18] and Deng et al. [19] neglected the deterioration in strength of LRBs due to temperature rise in the lead core under cyclic motion. Thus, presented results are based on bounding analyses where hysteretic properties such as strength and stiffness of LRB do not change during the applied motion.

Detailed review of the literature for seismic response of LRB isolated bridges at low temperatures revealed that (i) results regarding the variation in mechanical properties of LRB isolators are based on either small- or moderate-size bearings (ii) analytical models for isolator behavior at low temperature do not address the deteriorating hysteretic behavior of LRBs. Thus, there is a need to revisit the performance of LRB isolated bridges subjected to ground motion excitations at low temperature.

The objective of this study is to determine the variation in seismic performance of an LRB isolated bridge considering the change in mechanical properties of LRB when exposed to low temperature. For this purpose, first, a large-size LRB was tested at both room (20°C) and low

(-30°C) temperatures under dynamic conditions. Change in mechanical properties of tested LRB was reported. Then, experimental data is used to verify the success of analytical model employed to idealize hysteretic response of LRBs. Accordingly, deteriorating hysteretic behaviors of the LRB obtained from both experiments and analytical models were compared with each other. Once the use of analytical model to idealize nonlinear hysteretic behavior of LRBs has been shown to be appropriate for both room and low temperature conditions, a representative bridge seismically isolated by LRBs, was analyzed under the effect of both near-field and large-magnitude small-distance ground motions. In the analyses, both horizontal components of selected ground motions were subjected to structural model simultaneously. Maximum isolator displacements (MIDs), and maximum isolator forces (MIFs) were the response quantities used to quantify the variation in seismic performance of LRB isolated bridge at low temperature.

## 2 EXPERIMENT OF A LARGE-SIZE LEAD RUBBER BEARING

### 2.1 Specimen

The bearing tested in this study is a large-size LRB with rubber and lead core diameters of 1020 mm and 190 mm, respectively. Height of the bearing is 436 mm including the top and bottom plates together with the end shim at the top. It is composed of 28 layers of rubber each of which has 10 mm thickness with a total rubber height of 280 mm. Geometrical properties of the tested LRB is presented in Figure 1.

Figure 1- Section cut of test specimen

### 2.2 Loading Device

Tests were conducted at ESQUAKE Seismic Isolator Test Laboratory of Eskisehir Technical University. Figure 2.a, b shows the air-conditioned room and test setup used in the experiment, respectively. The temperature capacity of the air conditioning room is between -40°C and +50°C. In the loading device, vertical actuator has the maximum capacity of 20000kN load. In the horizontal actuator, the maximum capacity of 2000kN load and  $\pm 600$  mm stroke with 1000mm/s velocity.

### 2.3 Loading Method

In order to determine the mechanical properties of the specimen, its hysteretic response in shear was recorded under a constant compressive load. Accordingly, the LRB was subjected to three cycles of sinusoidal motion with amplitude equals to 280 mm that corresponds to

100% shear strain. Frequency of the motion was 0.1 Hz where the maximum velocity is 176 mm/s. The LRB was first tested at a temperature of 20°C after conditioning for 24 hours inside the laboratory and tested again at a temperature of -30°C after conditioning for 24 hours inside the air-conditioned room (Figure 2.a). In all experiments described in this paper, vertical load is equal to 4500kN (6MPa normal stress).

Figure 2 - (a) Air-conditioned room and (b) seismic isolator test setup of ESQUAKE

## 2.4 Test Results

Mechanical properties of the tested LRB such as post-yield stiffness ( $K_d$ ), characteristic strength ( $Q_d$ ), effective stiffness ( $K_{eff}$ ), energy dissipation capacity ( $EDC$ ) and effective damping ratio ( $\xi_{eff}$ ) are computed by means of Equations (1)-(4) provided by ISO 22762-1 [20]. In Equations (1) and (2),  $Q_1'$ ,  $Q_1''$ ,  $Q_2'$  and  $Q_2''$  are the isolator forces at 50% of the maximum positive and negative horizontal displacements  $d_{max}$  and  $d_{min}$ .  $Q_1$  and  $Q_2$  of Equation (3) are the isolator forces at  $d_{max}$  and  $d_{min}$ , respectively (see Figure 3). The calculated test results of LRB isolator are presented in Table 1 for temperatures of 20°C and -30°C.

Figure 3 - Force-displacement definitions for LRBs.

$$Q_d = \left[ \frac{Q_1'' d_{max}/2 - Q_1' d_{min}/2}{(d_{max} - d_{min})/2} - \frac{Q_2' d_{max}/2 - Q_2'' d_{min}/2}{(d_{max} - d_{min})/2} \right] / 2 \quad (1)$$

$$K_d = \left[ \frac{Q_1' - Q_1''}{(d_{\max} - d_{\min})/2} + \frac{Q_2'' - Q_2'}{(d_{\max} - d_{\min})/2} \right] / 2 \quad (2)$$

$$K_{eff} = \left[ \frac{Q_1 - Q_2}{d_{\max} - d_{\min}} \right] \quad (3)$$

$$\xi = \left[ \frac{EDC}{\pi(F_{\max} D_{\max} + F_{\min} D_{\min})} \right] \quad (4)$$

Temperature	Cycle	$Q_d$ (kN)	$K_d$ (kN/m)	$K_{eff}$ (kN/m)	$EDC$ (kN·m)	$\xi_{eff}$ (%)
-30°C	1	489	2020	3441	504	0.29
	2	414	1919	3100	433	0.28
	3	372	1864	2913	382	0.26
20°C	1	324	1833	2706	335	0.25
	2	286	1796	2510	297	0.24
	3	260	1766	2392	264	0.22

Table 1: Mechanical properties of LRB at 20°C and -30°C.

According to the test results, it can be revealed that characteristic strength  $Q_d$  of the tested LRB increases when the temperature drops down to -30°C. The amount of amplification in  $Q_d$  is 50% for the first cycle whereas it is 45% and 43% for the second and third cycles, respectively. Similarly, post-yield stiffness  $K_d$  of the LRB increases 10% as the temperature decreases for first cycle. On the other hand, energy dissipation capacity (EDC), increases as the temperature decreases. In parallel, reducing the temperature from 20°C to -30°C contributes to an increase in effective damping ratio  $\xi_{eff}$  equal to 17% for the first cycle. Considering the obtained results, it can be noted that variation in mechanical properties of LRB is not constant while different air temperatures expose to the bearing.

### 3 ANALYTICAL REPRESENTATION OF LRB ISOLATED BRIDGE MODEL

#### 3.1 Hysteretic Response of LRB

The analytical representation of the tested LRB were performed by means of OpenSees [21] structural analysis program. Force-displacement curves obtained from experiments are compared with the analytical ones for both 20°C and -30°C. Figure 4 shows that hysteretic response of the tested LRB can be idealized realistically with great success in the analyses regardless of the ambient temperature. During the LRB model, mathematical representation proposed by Kalpakidis and Constantinou [22] can be considered to modify the initial strength of lead as a function of lead core temperature. Their model considers the instantaneous temperature rise in the lead core and allows calculating the reduction in strength of isolator via reducing the initial yield stress of the lead, instantly. For detailed information please refer to Kalpakidis and Constantinou [22].

#### 3.2 Bridge Model

Analyzed bridge model is a cast-in-place concrete box girder bridge with a 30-degree skew. The length of the bridge is 97.5m and has three spans with lengths of 30.5m, 36.5m and

30.5m. Intermediate bents consist of two 1.22m circular columns and a cap beam with dimensions of 1.22m x 1.83m. The total weight of the bridge above the isolation level is 24956 kN (box girder and each diaphragm weigh 229 kN/m and 657 kN, respectively). The section at one of the intermediate bents is presented in Figure 5.a.

Figure 4: Comparison of experimental and analytical hysteretic curves of LRB tested at a) 20°C and b) -30°C.

Figure 5: (a) bent geometry and (b) analytical model of the bent.

As shown in Figure 5.a, seismic isolation system is composed of two LRBs at each abutment and pier with a total of eight isolators. They are modeled by deteriorating hysteretic behavior. In order to consider nonlinear bidirectional interaction of LRBs in case of simultaneous excitations of ground motions in both horizontal directions, bidirectional hysteretic model developed by Park et al [23] was employed in the model.

The bridge superstructure was assumed to have infinite in-plane rigidity [24-25]. Analytical representation of the bridge bent is given in Figure 5.b where  $M_{\text{superstructure}}$  is defined based on the tributary weight of the superstructure + the additional weight of the diaphragm and equals to 850t (isolation period based on the post-yield stiffness of the tested LRB at 20°C is 3s). Total mass of the bent components,  $M_{\text{bent}}$ , is lumped equally at the column tops. In the analytical model, member rigid end zone matter is also taken into account to represent the bent stiffness properly. The bridge superstructure and columns are modeled as elastic based on the assumption that structure remains within the elastic range due to seismic isolation by means of *elasticbeamcolumn* element of OpenSees [21]. Accordingly, the elastic

modulus of concrete is taken as 24820 MPa. Bridge structure is assumed to be fixed at the foundation level.

#### 4 GROUND MOTIONS

Two sets of ground motions previously used by Warn and Whittaker [24], were considered in the analyses. Each ground motion set is composed of 10 pairs of record. They were clustered to represent characteristics of near-field (NF) and large-magnitude small-distance (LMSD) records. The magnitudes of ground motions grouped as near-field are in between 6.7 and 7.6 with closest distances to the fault rupture less than 10 km. On the other hand, large-magnitude small-distance ground motions have magnitudes greater than 6.5 while closest distances to fault rupture are in between 10 km and 30 km. Tables 2 and 3 give the characteristics of the considered ground motions where PGA, PGV and PGD stands for peak ground acceleration, peak ground velocity and peak ground displacement, respectively.

## 5 DYNAMIC ANALYSES RESULTS

Nonlinear response history analyses were performed in OpenSees [21] with due consideration of deteriorating hysteretic representation of LRBs under bidirectional excitations of ground motions given Tables 2 and 3 in order to evaluate the variation in response quantities of the SIB due to change in environmental temperature. Accordingly, maximum isolator displacements (MIDs) and base shears in the pier are presented in a comparative manner for 20°C and -30°C.

### 5.1 Maximum Isolator Displacement

This section presents the observations related to variation of MID of the analyzed structural system due to change in ambient temperature. Figure 6 shows the comparison of MIDs obtained for 20°C and -30°C for both ground motion sets of NF and LMSD. Averages of MIDs recorded for all of the considered ground motion records are also given in Figure 6

where MIDs were calculated by taking the maxima of  $\sqrt{(D_x^2 + D_y^2)}$ . Here,  $D_x$  and  $D_y$  are the isolator displacements in horizontal x- and y-directions, respectively. Figure 6.a, at which MIDs for NF ground motions are presented, reveals that MID reduces significantly when the ambient temperature drops down from 20°C to -30°C. The amount of reductions in MID ranges from 8% to 53% with an average value of 19%. Similar comparison for LMSD ground motions is given in Figure 6.b. In this case, the amounts of change in MIDs for individual ground motion records range from 33% to -52% with an average of -16%.

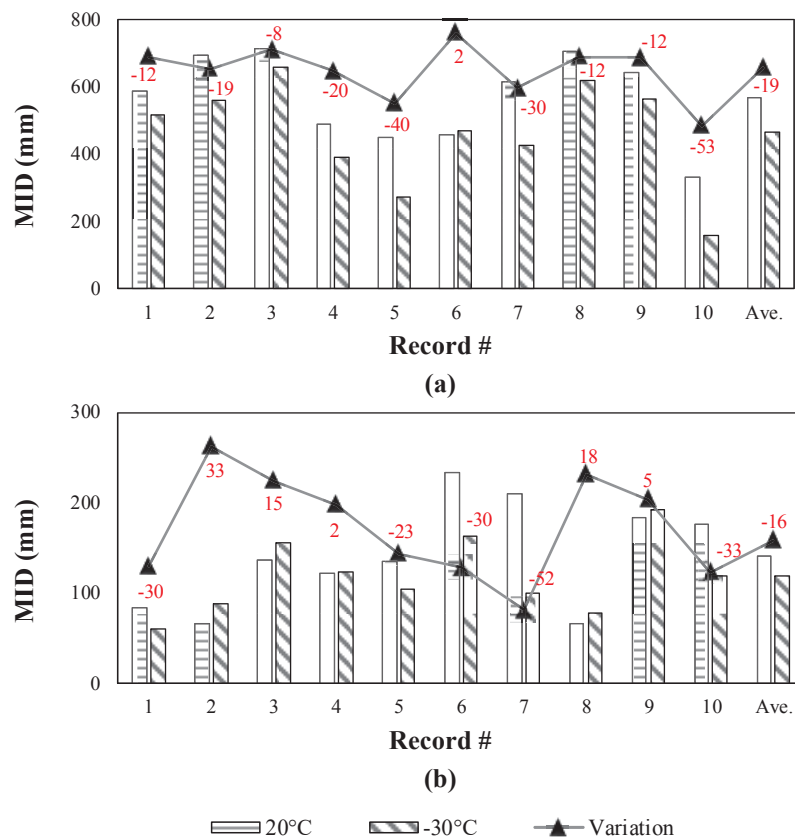

Figure 6: Comparison of MIDs for (a) NF and (b) LMSD ground motions at 20°C and -30°C.

## 5.2 Maximum Base Shear in the Piers

In this section, variation of base shears acting on each column of the bridge is presented in Figure 7 as a function of ambient temperature and seismicity level. For near field ground motions, Figure 7.a shows that the amounts of variation in isolator force are in between -13% to 20% when temperature decreases from 20°C to -30°C. However, it is interesting to observe that when the averages of base shears are of concern, they are identical for both 20°C to -30°C with a magnitude of 1248 kN. Although the initial strength and stiffness of isolator increases due to reduced ambient temperature, the average shear force does not change for both 20°C to -30°C. Figure 7.b is depicted to investigate the variation of isolator force for large-magnitude small-distance ground motion set when temperature is reduced from 20°C to -30°C. Figure 7.b reveals that although the average value of amplification in isolator force is calculated as 23%, for the selected ground motions it may be up to 60%, individually.

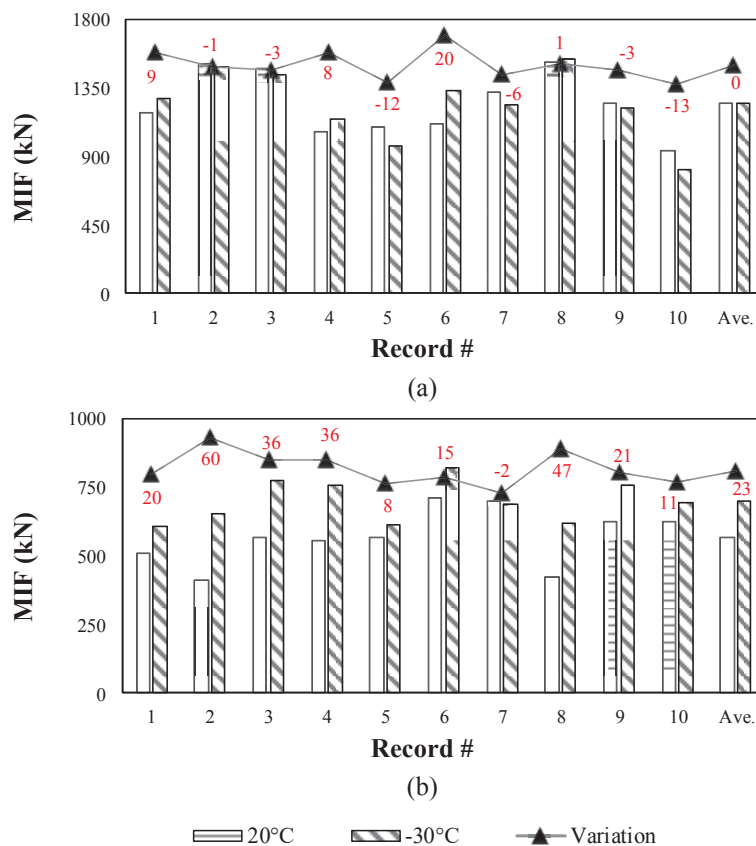

Figure 7: Comparison of MIFs for (a) NF and (b) LMSD ground motions at 20°C and -30°C.

## 6 CONCLUSIONS

In this paper, variation in response parameters of a seismically isolated bridge is studied under the effect of low (-30°C) and air temperature (20°C). The major findings showed that MIDs obtained for LRB properties of 20°C are about 20% larger than the ones obtained for -30°C, in an average sense. Furthermore, average MSF obtained for near-field ground motions at 20°C and -30°C are identical. However, for large-magnitude-small-distance ground motions, MSF of -30°C is almost 25% larger than that of 20°C.

### Abstract

*This paper proposes a Stiff Seismic Base Absorber (SBA). An inerter is first implemented, connecting directly the structure to the ground. This results to the decrease of the natural frequency of the structure, without the decrease of the structural stiffness. Parallel, an extension of the KDamper is used, in order to increase the apparent damping behavior of the inerter. A negative stiffness (NS) element connects the additional mass of the SBA to the structure and a positive stiffness element the additional mass to the base. Also, an artificial damper is placed in parallel with each stiffness element. The design of the SBA is based on an appropriate optimization approach, which includes the following novel features: i) the SBA foresees variation in all stiffness elements, ii) the optimal system parameters are selected based on engineering criteria with proper constraints and limitations to the system dynamic responses, iii) the earthquake input motion is selected according to the seismic design codes, iv) for the NS element, a displacement-dependent non-linear mechanism is proposed realized by a pre-compressed leaf spring instead of conventional coil springs. Compared to other vibration absorbers, the SBA presents a number of advantages. An improved superstructure dynamic behavior is observed combined with small base displacements, in the order of a few centimeters. The drastically reduced base displacements render the implementation of the SBA feasible using conventional structural elements. As a result, the SBA is a possible retrofitting option for seismic protection.*

## 1 INTRODUCTION

In recent years, seismic codes have been significantly modified with the intention to lead to robust structures that perform better under seismic loading. To this end, the reduction of structural responses induced by environmental excitations has become a subject of intensive research. Many structural control concepts have been evolved for this purpose, and quite a few of them have been implemented in practice. They include the mitigation of vibrations in structures due to unexpected large environmental hazards, the retrofitting of existing structures, the protection of seismic equipment and important secondary systems and the provision of new principles for structural design against environmental loading. These structural control systems can be broadly classified into active, passive, semi-active and hybrid control systems.

Seismic base isolation is considered perhaps the most efficient design approach of anti-seismic protection because it relies on reducing the seismic demand rather than increasing the structure's rigidity by adding shear walls or braced frames. It has led to earthquake-resistant design of building structures [1, 2], bridges [3] and industrial facilities [4-6]. The seismic isolation system is installed between the foundation and the upper structure providing horizontal isolation and reducing seismic wave propagation into the structure. This way, the fundamental period of the system is significantly longer and thus the structural peak accelerations are reduced. Over the years, a number of isolation devices such as elastomeric bearings, frictional/sliding bearings and roller bearings have been developed [7-10]. However, this type of isolation is inefficient for high rise structures, cannot be applied partially to structures unlike other retrofitting and is not suitable for buildings rested on soft soil. Also, under long-period ground motions large displacements are produced to the base isolated building that can provoke structural pounding leading to a serious risk of damage or even collapse of the building.

Due to these disadvantages, alternative vibration control methods have been developed that combine the conventional base isolation (BI) scheme with other active or passive control systems, including: (i) Tuned Mass Dampers (TMDs), (ii) Inerters, (iii) Negative Stiffness Devices (NSD) and "Quazi Zero Stiffness" (QZS) oscillators and (iv) Mechanisms combining Negative Stiffness and Absorbers/KDampers.

A Tuned Mass Damper (TMD) is a device consisting of a mass, a stiffness element and a damper that is attached to the structure in order to reduce its dynamic response. The natural frequency of the TMD is tuned in resonance with the fundamental mode of the primary structure, so that when that frequency is excited, the damper will resonate out of phase with the structural motion. Thus, a large amount of the structural vibrating energy induced by wind and earthquake loads is transferred to the TMD and then dissipated by damping. TMDs have been installed in a great number of tall buildings [11-13] in order to reduce vibrations caused by seismic or wind loading in main systems. Also, during last years a novel control strategy combining BI and TMD [14-18] has been developed. Although TMDs are effective and reliable, their usage presents a number of drawbacks, including: (i) detuning, caused by environmental influences, which can lead to a significant loss of system's performance [19], (ii) the requirement for large additional mass or large space for their installation, (iii) the restriction of the maximum weight that can be practically placed on the top of the structure and (iv) the large TMD displacements [20], which in some cases exceed even the base displacements.

A more efficient alternative is a new passive BI control strategy combining the TMD with an inerter (TMDI) [21, 22]. In this concept, the additional mass of the TMD is connected to the supporting ground by an inerter device [23]. The inerter is a two terminal element which has the property that force generated at its ends is proportional to the relative acceleration between them. The TMDI takes advantage of the "mass amplification effect" of the inerter to achieve enhanced performance compared to the classical TMD. As a result, the proposed

TMDI configuration can either replace part of the TMD vibrating mass to achieve lightweight passive vibration control solutions, or improve the performance of the classical TMD for a given additional mass. Still, to work effectively, all considered devices have to be precisely calibrated which can be challenging or even impossible in some cases. Moreover, proposed TMDs with inerters suffer from susceptibility to detuning.

A parallel direction to the various TMD approaches is the concept of negative stiffness (NS) vibration isolation devices. These devices, due to their promising potentials into the field of vibration control, they have attracted a significant amount of attention in research areas. They use a passive mechanical system to generate negative stiffness without the need of any external power supply. Negative stiffness is defined as a force that assists motion instead of opposing it. The concept of negative stiffness elements (or “anti-springs”) for vibration isolation was first introduced in the pioneering publications of Molyneaux [24] and later on, in the milestone developments of Platus [25]. The main feature of these approaches is the significant reduction of the isolator’s stiffness, which consequently leads to the decrease of the natural frequency of the system (the system’s natural period is increased) even at almost zero levels, resulting in configurations called “Quasi-Zero Stiffness” (QZS) oscillators [26]. In the field of seismic protection of structures, QZS oscillators have a wide variety of applications [27–30]. The primary disadvantage of these devices is their requirement for a drastic reduction of the structure’s stiffness almost to zero levels, limiting its static load capacity.

In an effort to exploit the advantages of TMDs and QZS oscillators, a novel passive vibration isolation, and damping concept, termed as KDamper, has been first introduced in Antoniadis et al. [31]. This device consists of an additional mass, a damper, a spring and is characterized by the incorporation of a negative stiffness element. The force produced from this NS element during excitations, increase indirectly the inertia effect of the additional mass, abolishing the need of a large additional mass unlike TMD in order to work efficiently. The presence of this mass serves in mitigating the effects of a vibrating load, operating as an energy dissipation mechanism. This oscillator exhibits extraordinary damping properties and is designed to maintain the same overall static stiffness as a traditional reference original oscillator, contrary to the QZS mechanism. Also it overcomes the sensitivity problems of TMDs as the tuning is mainly controlled by the negative stiffness element’s parameters. The KDamper has been examined for the seismic protection of several structural systems, such as bridges [32–36], wind turbines [37, 38] and buildings [39, 40]. In addition, it has effectively implemented as an Absorption Base (KDAB) in the bases of structures [41–46].

In this paper a Stiff Seismic Base Absorber (SBA) is proposed, that combines an extension of the KDamper and an inerter, connected in parallel. The Extension of the KDamper, termed as EKD [47] is an alternative configuration based on the initial design, and aims to further improve its dynamic behavior. The purpose of the EKD is to increase the damping behavior of the inerter and to further reduce the structural relative displacements under seismic loading. In section 2 of this paper, a novel negative stiffness mechanism is proposed for the realization of the NS element, which includes a pre-compressed leaf spring instead of conventional stiffness elements. The properties, parameters and nonlinear equations of motion of the SBA implemented in a multi-story building are presented in section 3. However, the complexity of the SBA renders the conventional min-max approaches ineffective for the determination of the optimal parameters of the device. Therefore, section 4 presents the proposed optimization procedure of the SBA based on engineering criteria with proper geometrical and constructional limitations. In section 5, the effectiveness of the SBA is compared with a conventional and a highly damped base isolated structure, through a numerical example of a building subjected to artificial accelerograms designed to match the EC8 acceleration response spectra. Finally, an indicative design is proposed for the examined configuration.

## 2 REALIZATION OF THE NEGATIVE STIFFNESS MECHANISM

Negative stiffness in applications concerning vibration isolation is mainly achieved by appropriate mechanical designs involving positive stiffness pre-stressed elastic components, such as post-buckled beams, plates, shells and pre-compressed springs arranged in specific geometrical configurations [48-50]. Alternatively to elastic forces, the negative stiffness effect can also be produced by gravitational [51], magnetic [52] or electromagnetic forces [53]. However, elastic forces tend to be the only viable option when dealing with seismic effects mitigation on buildings or bridges, where the required values of negative stiffness are very high.

In this chapter, the proposed configuration for the realization of the negative stiffness is presented. The novelty of this mechanism is that a pre-compressed leaf spring is involved, which can withstand huge vertical loads compared to conventional springs. It is an effective mechanism with simple design and has the ability to easily control the negative stiffness value.

### 2.1 Proposed configuration

The negative stiffness mechanism under consideration is depicted in Figure (1), where any other part of the EKD device is excluded. The system comprises a vertical stiffness element (spring), one end of which is fixed and the other is hinged to a metal rod. The rod has length  $a$  and its upper end is connected with a roller support which allows the horizontal displacement  $u$  during the earthquake.

Figure 1: Schematic representation of the negative stiffness mechanism of the Extended KDamper.

The vertical stiffness element has initial length  $l_{HI}$  (Figure (1a)), stiffness  $k_T$  and reaches its maximum compression when it's collinear with the rod (Figure (1b)). This position, termed as undeformed configuration, is also the unstable equilibrium position where the equivalent negative stiffness value  $k_N$  is maximized. When the mechanism deforms in one direction, the rod rotates and creates a force that assists motion (Figure (1d)), generating thereby the negative stiffness mechanism. In this position the value of the equivalent negative stiffness is decreased and reaches its minimum value when  $u=u_{max}$ . The perturbed position is depicted in Figure (1), along with the necessary notation concerning the various displacements and dimensions of the system.

From the length  $a$  of the rod, the total height  $b$  of the mechanism, the initial free length  $l_{HI}$  of the spring and for maximum horizontal displacement  $u=u_{\max}$ , a dimensionless parameter is defined as:

$$c_I = \frac{b-l_{HI}}{a} \quad (1)$$

From the geometry of the mechanism results:

$$a_x = \sqrt{a^2 - u^2} \quad (2)$$

$$\varphi = \arctan(u / a_x) \quad (3)$$

$$l_H(u) = b - a_x \quad (4)$$

where  $l_H(u)$  is the varying length of the vertical stiffness element during the oscillation of the mechanism. The potential energy, the exerted force and the equivalent negative stiffness of the system respectively are given by:

$$U_N(u) = \frac{1}{2} k_T [l_H(u) - l_{HI}]^2 \quad (5)$$

$$f_N(u) = \frac{dU_N}{du} = -k_T \left[ 1 - c_I \frac{1}{\sqrt{1 - (u/a)^2}} \right] u \quad (6)$$

$$k_N(u) = \frac{df_N}{du} = -k_T \left[ 1 - c_I \frac{1}{[1 - (u/a)^2]^{3/2}} \right] \quad (7)$$

The maximized value of the equivalent negative stiffness which occurs at the equilibrium position of the mechanism ( $u=0$ ) and which corresponds to the desired value of  $k_N$  as calculated from the dimensioning of the Extended KDamper is:

$$k_N(u=0) = -k_T (1 - c_I) \quad (8)$$

The term  $(1 - c_I)$  by exploiting Eq. (1) becomes

$$1 - c_I = 1 - \frac{b - l_{HI}}{a} = \frac{l_{HI} - (b - a)}{a} = \frac{x_{T,\max}}{a} \Rightarrow c_I = 1 - \frac{x_{T,\max}}{a} \quad (9)$$

where  $x_{T,\max}$  is the maximum deformation of the vertical stiffness element. Therefore Eq. (8) becomes:

$$k_N(u=0) = -k_T \frac{x_{T,\max}}{a} \quad (10)$$

By dividing Eq. (7) and Eq. (10) and by using Eq. (9), the negative stiffness ratio is defined as:

$$r_k = \frac{k_N(u)}{k_N(u=0)} = \frac{1 - \left( 1 - \frac{x_{T,\max}}{a} \right) \frac{1}{[1 - (u/a)^2]^{3/2}}}{x_{T,\max} / a} \quad (11)$$

This ratio expresses the variation in the value of the negative stiffness during the motion from the position  $u=0$  up to position  $u=u_{\max}$ . Optimally we aim this ratio to be larger than 0.75.

The vertical and horizontal forces applied to the rod due the oscillation of the system are given respectively as:

$$F_T = k_T x_T \quad (12)$$

$$F_B = F_T \tan \varphi \quad (13)$$

where  $x_T$  is the deformation of the spring from its initial free length. The vertical force  $F_T$  becomes maximum when  $x_T = x_{T,\max}$ , while the horizontal force  $F_B$  becomes maximum when  $u = u_{\max}$ .

## 2.2 Vertical stiffness element of the proposed configuration

The vertical stiffness element of the mechanism with stiffness  $k_T$  is realized by a leaf spring which is composed of several parallel metal leaves (sheets) mounted on top of each other in multiple layers and groups. These leaves have rectangular section and they held together by metal clips attached at the center and at either end. Due to sheer amount of metal layered together, the leaf spring can take huge vertical loads due to its tight-knit structure.

Each layer of the leaf spring consists of two metal sheets with length  $L$  and can be approximated by a center loaded beam fixed at both ends as depicted in Figure (2).

Figure 2: Center loaded fixed-fixed beam.

The bending area moment of inertia, of the beam's cross section  $A = wh$  is defined as:

$$I = \frac{wh^3}{12} \quad (14)$$

The bending stiffness of the beam can be expressed as:

$$k_B = \frac{24EI}{L^3} \quad (15)$$

or by substituting Eq. (14):

$$k_B = 2Ew \left( \frac{h}{L} \right)^3 \quad (16)$$

From Hooke's Law,  $F = k_B \cdot x_B$ , the bending deflection at the center of the beam is calculated as:

$$x_B = \frac{FL^3}{24EI} \quad (17)$$

The maximum stress ( $y = h/2$ ) due to the bending moment  $M = FL/4$  resulting from the application of the center loading ( $x = L$ ) is calculated as:

$$\sigma_{\max} = \frac{3Eh}{L^2} x_B \quad (18)$$

which must be lower than the yield stress  $\sigma_y$  of the leaf spring material.

The overall stiffness of the leaf spring consisting of such leafs/beams connected in various configurations is defined as:

$$k_T = \frac{N_B}{2N_G} k_B \quad (19)$$

where  $N_B$  is the number of parallel leaves/beams and  $N_G$  is the number of groups connected in series as depicted in Figure (3). Simultaneously, the resulting range of motion comes as:

$$x_T = 2N_G x_B \quad (20)$$

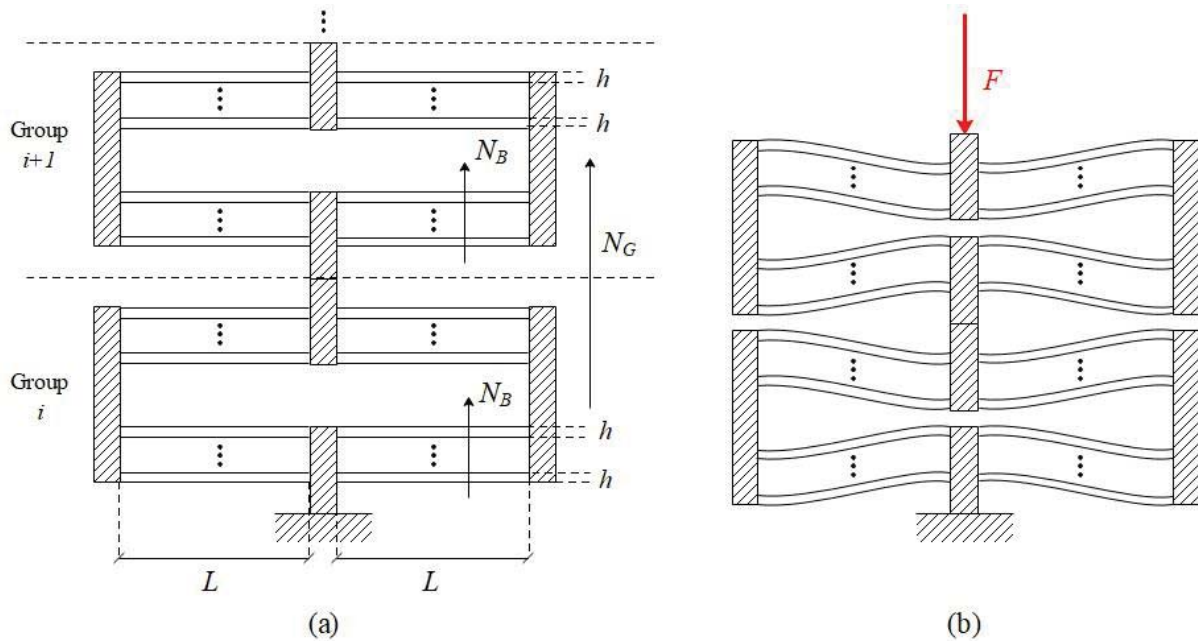

Figure 3: Schematic representation of a leaf spring configuration (a) undeformed and (b) deformed.

### 2.3 Implementation example

A theoretical implementation example of this NS mechanism is presented in this subsection. The general purpose of the proposed SBA is the seismic protection of multi-story building structures. Therefore, a reference mass of 50 tn (structural mass) is assumed for the design of the SBA mechanism. This way, multiple SBA device can be implemented with respect to the total superstructure mass, as SBAs can operate in parallel. The reference values of the NS the dynamic responses relative to the operation of the SBA used in this example, are obtained from [47]. Figure (4a) presents the equivalent NS ratio ( $k_N/k_N(u=0)$ ) over the dimensionless relative displacement between the two terminals of the NS configuration ( $u/u_{\max}$ ), obtained by the proposed mechanism presented previously. It is observed that this mechanism is sufficient in keeping the NS in acceptable levels ( $>0.75$ ) for all the operating range. Figure (4b) presents the ratio of the vertical deformation of the leaf spring, as a function of  $u/u_{\max}$ . It is observed that substantial vertical load can be supported due to the properties of the leaf spring.

Figure 4: Numerical analysis of the NS element: (a) equivalent NS, (b) vertical deformation of the leaf spring.

### 3 SEISMIC BASE ABSORBER CONFIGURATION

In this section the proposed Seismic Base Absorber (SBA) configuration is presented. The SBA is a seismic isolation device implemented in the base of the structure, composed of an Extended KDamper (EKD) and an inerter connected in parallel. The EKD is an extension of the already developed KDamper [32–46], which in previous studies has indicated a significant improvement in the dynamic behavior of a structure both in terms of absolute accelerations and relative displacements compared to other base isolation scenarios (rubber bearings, QZS oscillators, TMDs, etc.). The proposed extension exhibits even a better performance, while it foresees variation in all stiffness elements, while in the KDamper concept only the negative stiffness variation is taken into consideration. Furthermore, the negative stiffness element stroke, which is critical for the design of the whole configuration is dramatically reduced. Concerning the proposed SBA design, the EKD is used in order to increase the damping behavior of the inerter.

The basic idea behind the proposed SBA configuration is the decreasing of the nominal frequency of the system achieved with inerter and subsequently the control of the structural relative displacements with the extraordinary damping properties that EKD offers. Also, the small base displacements and NS element stroke, render the implementation of the proposed control system feasible, using conventional structural elements, making it the more efficient retrofitting option for horizontal seismic protection.

#### 3.1 Parameters of the SBA

The implementation of the SBA in the base of a multi-story building structure for horizontal seismic protection is depicted in Figure (5a). In the next sections, the performance of the SBA in seismic isolation will be compared with the performance of Lead Rubber Bearings (LRB) implemented in the base of the structure (Figure (5b)), which is the most commonly used seismic isolation system. As depicted in Figure (5a), the SBA consists of a negative stiffness (NS) element  $k_{NS}$ , a positive stiffness (PS) element  $k_{PS}$  and two artificial dampers with damping coefficients  $c_{NS}$ ,  $c_{PS}$  placed in parallel to  $k_{NS}$  and  $k_{PS}$  respectively. Compared to the KDamper, the NS element connects the additional mass  $m_D$  to the structure, instead of the PS element, which now connects the  $m_D$  to the ground. The inerter with constant  $b_I$  (measured in kilograms), is parallel to the EKD. Finally, the positive stiffness  $k_R$  works independent from the other parts of the device and there are numerous alternatives for its realization.

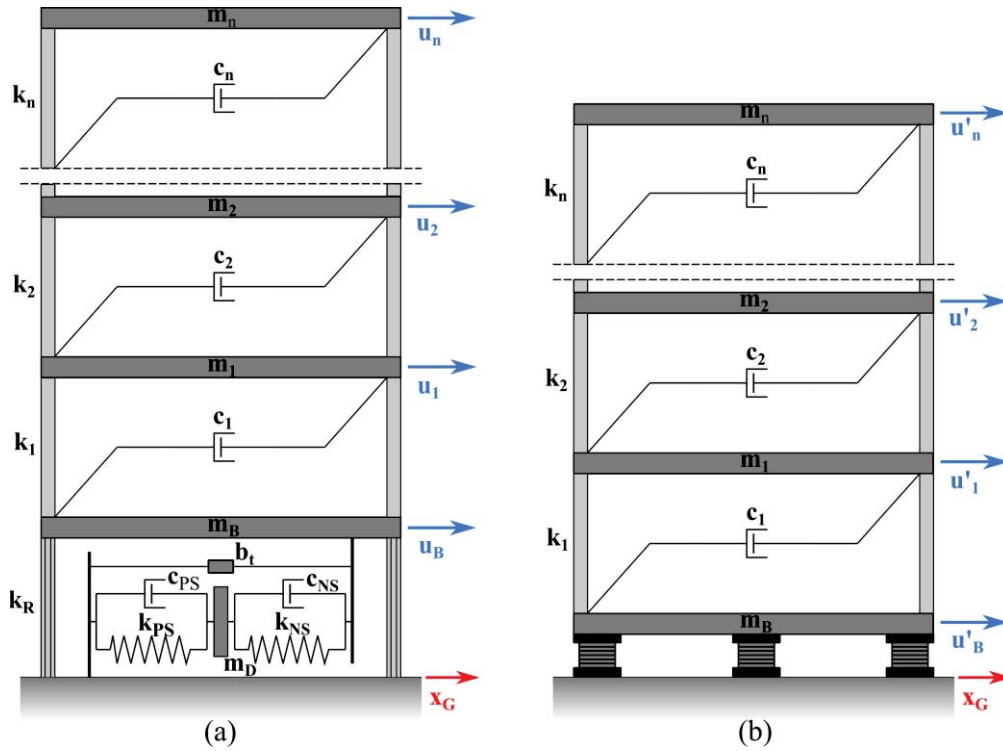

Figure 5: Multi-story building structure with (a) the proposed SBA configuration and (b) the conventional LRB, implemented in its base.

The basic requirement of the proposed configuration of the SBA is that the overall stiffness of the system is maintained:

$$k_R + \frac{k_{PS}k_{NS}}{k_{PS} + k_{NS}} = k_0 = (2\pi f_0)^2 m_{total} \quad (21)$$

where  $k_0$  is the equivalent static stiffness of the SBA,  $f_0$  the nominal frequency of the SBA and  $m_{total}$  the overall mass of the structure including the base and the additional mass. This requirement overcomes the fundamental disadvantage of QZS oscillators, in which the overall stiffness of the system is reduced, limiting its static load capacity. Theoretically the values of  $k_{NS}$ ,  $k_{PS}$  and  $k_R$ , are selected according to Eq. (21) in order to ensure the static stability of the system. Nevertheless, these values may present significant variations in practice due to a number of reasons (temperature fluctuations, manufacturing tolerances or non-linear behavior) which must be taken into account. As a consequence, a simultaneous increase of the absolute value of  $k_{NS}$  by a factor of  $\varepsilon_{NS}$  and a decrease of the values of  $k_{PS}$  or  $k_R$  by a factor of  $\varepsilon_{PS}$  and  $\varepsilon_R$ , respectively, may result in an unstable system. This occurs when:

$$R \times k_R + \frac{P \times k_{PS} \times N \times k_{NS}}{P \times k_{PS} + N \times k_{NS}} = 0 \quad (22)$$

where  $R=1-\varepsilon_R$ ,  $P=1-\varepsilon_{PS}$  and  $N=1+\varepsilon_{NS}$ . Assuming the negative stiffness ratio as  $kn=k_{NS}/k_0$ , or the absolute value of  $k_{NS}$  known, the rest of the stiffness elements result from Eq. (21), (22) as:

$$\begin{aligned} kr &= \frac{-b - \sqrt{b^2 - 4 \times a \times c}}{2a} \Rightarrow k_R = kr \times k_0 \\ kp &= \frac{kn - kr \times kn}{kr + kn - 1} \Rightarrow k_{PS} = kp \times k_0 \end{aligned} \quad (23)$$

where the parameters  $a$ ,  $b$  and  $c$  are defined as:

$$\begin{aligned} a &= R(P - N) \\ b &= kn \times N(P - R) + R(N - P) \\ c &= -P \times N \times kn \end{aligned} \quad (24)$$

Finally, assuming that the additional mass,  $m_D$ , and the variations  $\varepsilon_{NS}$ ,  $\varepsilon_{PS}$  and  $\varepsilon_R$  of the stiffness elements are known, the unknown parameters of the system are: i) the nominal KDamper frequency  $f_0$ , ii) the negative stiffness ratio  $kn$  or the value of the negative stiffness element  $k_N$  iii) the damping coefficients  $c_{NS}$  and  $c_{PS}$  and iv) the coefficient  $b_t$  of the inerter.

### 3.2 Equations of motion of the system

The structure illustrated in Figure (5) is based on the following assumptions: (i) the total building's mass is concentrated at floor level, (ii) the slabs and girders on the floors are rigid compared to the columns, (iii) the columns are weightless and their axial deformation is neglected providing only lateral stiffness, (iv) the SSI effects are not accounted. Consequently, the superstructure has  $n$  dynamic DOFs, represented by the relative base displacements ( $u_i$ ) of the  $n$ -stories. The structure has 2 more DOFs due to the relative to the ground displacement of the base ( $u_B$ ) and the additional mass ( $u_D$ ). The vector of displacements is defined as:

$$[u(t)]_{(n+2) \times 1}^T = \left[ [u_s(t)]_n^T \quad u_B(t) \quad u_D(t) \right]_{(n+2) \times 1}^T \quad (25)$$

where  $[u_s(t)]_n^T = [u_1 \quad u_2 \quad \dots \quad u_n]_{n \times 1}^T$ . The equations of motion of the system depicted in Figure 5a for ground displacement  $x_G$  are expressed in a matrix form as:

$$[M][\ddot{u}] + [C][\dot{u}] + [K][u] = -[\tau]\ddot{x}_G \quad (26)$$

where:

$$\begin{aligned} [M]_{(n+2) \times (n+2)} &= \begin{bmatrix} [M_S]_{n \times n} & [0]_{n \times 1} & [0]_{n \times 1} \\ [0]_{1 \times n} & m_B + b_t & 0 \\ [0]_{1 \times n} & 0 & m_D \end{bmatrix}_{(n+2) \times (n+2)} \\ [K]_{(n+2) \times (n+2)} &= \begin{bmatrix} [K_S]_{n \times n} & [0]_{n \times 1} & [0]_{n \times 1} \\ [0]_{1 \times n} & k_{NS} + k_R & -k_{NS} \\ [0]_{1 \times n} & -k_{NS} & k_{NS} + k_{PS} \end{bmatrix}_{(n+2) \times (n+2)} \\ [C]_{(n+2) \times (n+2)} &= \begin{bmatrix} [C_S]_{n \times n} & [0]_{n \times 1} & [0]_{n \times 1} \\ [0]_{1 \times n} & c_{PS} & -c_{PS} \\ [0]_{1 \times n} & -c_{PS} & c_{PS} + c_{NS} \end{bmatrix}_{(n+2) \times (n+2)} \\ [\tau]_{(n+2) \times 1} &= \begin{bmatrix} [M][1]_{n \times 1} \\ m_B \\ m_D \end{bmatrix}_{(n+2) \times 1} \end{aligned} \quad (27)$$

The terms  $[M_S]$ ,  $[C_S]$  and  $[K_S]$  are the  $n$ -dimensional matrices of mass, damping and stiffness of the superstructure, respectively.

## 4 OPTIMIZATION OF THE PROPOSED SBA

Having established the nonlinear equations of motion Eq. (26), the next objective is to determine the optimal SBA parameters in order to attain the best possible vibration control strategy. Conventional min-max approaches ( $H_\infty$ ) [54] are rendered ineffective, due to the complexity of the SBA configuration, and the limitations imposed by the examined structural system and NS configuration (e.g., the one proposed in section 2). In this paper, the SBA is designed based on an engineering-criteria driven optimization procedure. This way, the geometrical and constructional limitations (e.g., large NS element stroke) imposed by the respective structural system are taken into account and the values of its individual components are retained in reasonable ranges. The optimal parameters of the SBA are evaluated using Harmony Search (HS), a novel metaheuristic algorithm [55], and the excitation input is selected according to the provisions of the EC8.

### 4.1 Artificial earthquake motion

In this section, a presentation of the details regarding the generation of artificial accelerograms based on the design response spectra is undertaken. For the purposes of this study, the approach followed is based on generating a sample of artificial accelerograms with acceleration response spectra in accordance with the EC8 design response spectra. Artificial, spectrum-compatible accelerograms are generated using the SeismoArtif Software [56]. In this paper, the artificial accelerograms are designed to match the EC8 response spectra with the following seismic properties: ground type C, spectral acceleration 0.36 g, spectrum type I and importance class II. A sample of 30 artificial accelerograms, with a mean PGA of 5.19  $m/sec^2$  is generated and plotted in Figure (6), and is compared to the EC8 response spectrum. An accurate match is observed (percentage deviation less than 10%) in the range of periods from 0.2 to 2 sec, which are considered relevant for the structural performance.

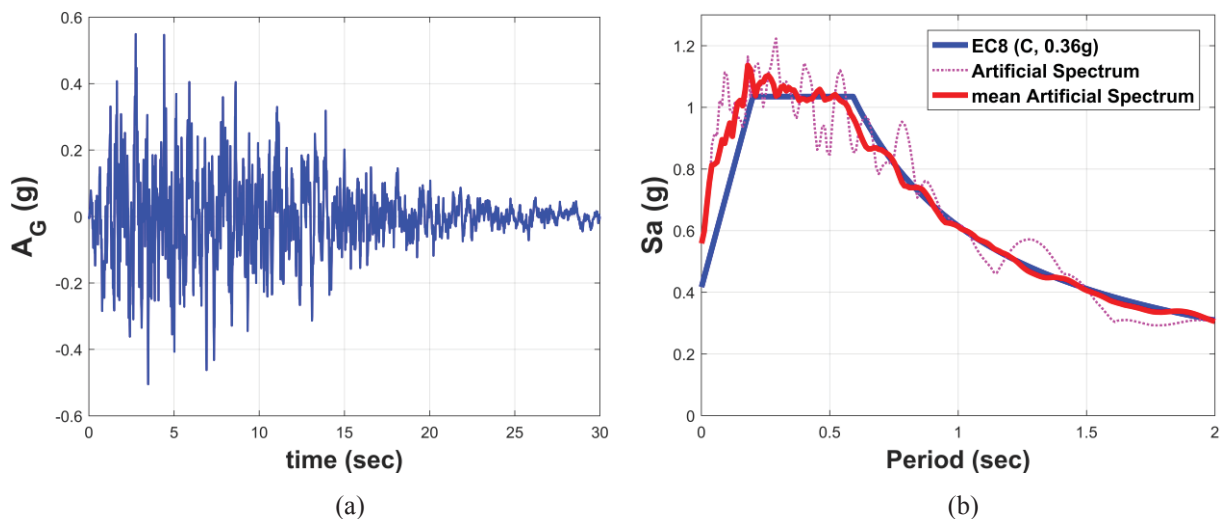

Figure 6: Generation of artificial spectrum compatible accelerograms. (a) Excitation sample, (b) mean acceleration response spectrum of 30 artificial samples compared to the EC8. Table 1

### 4.2 Optimization constraints and limitations based on engineering criteria

As stated in section 3.1, the independent design variables of the SBA are: i) the nominal SBA frequency  $f_0$ , the value of the NS element  $k_{NS}$ , the artificial dampers  $c_{NS}$ ,  $c_{PS}$ , and the interter coefficient  $b_t$ , assuming that the additional oscillating mass  $m_D$  and the variations of the stiffness elements  $\varepsilon_{NS}$ ,  $\varepsilon_{PS}$  and  $\varepsilon_R$  are known. The optimization problem is formed for the mean

of the maximum dynamic responses for the 30 artificial records of the database. The objective function and the constraints are selected from the geometrically non-linear time domain responses, as described below:

- i. Assign values to the known parameters (initial guess).
  - a) According to previous work of KDamper [46], an additional mass of 5% is efficient. In this paper, in an effort to drastically reduce the additional mass,  $m_D$  is selected as 0.1%.
  - b) The stability factors of the positive stiffness elements  $k_{PS}$ ,  $k_R$  are conservatively selected as 10%. The variation of the NS element  $k_{NS}$ , is selected according to the proposed configuration presented in section 2.1. 25% is a realistic value.

- ii. Set the objective function (OF) as the minimization of the mean of the maximum relative to the ground base displacements of the structure.

$$\min : \text{mean}[\max[abs(u_B)]] \quad (\text{OF}) \quad (28)$$

- iii. Set an acceleration filter (AF) as a constraint for the structure floors' absolute acceleration, expressed as a percentage of the mean PGA.

$$\text{mean}[\max[abs(a_i)]] \leq AF \times \text{mean}(PGA) \quad (i = 1, \dots, n) \quad (\text{Constraint 1}) \quad (29)$$

- iv. The NS element value and stroke are set as constraints, indicated from the proposed design of the NS configuration presented in section 2.3:

$$|k_{NS}| \leq 30 \text{ kN} / \text{m} / \text{tn} \quad (\text{Constraint 2}) \quad (30)$$

$$\text{mean}[\max[abs(u_B - u_D)]] \leq 0.07 \text{ m} \quad (\text{Constrain 3}) \quad (31)$$

- v. Set an upper limit for the damping coefficients  $c_{NS}$ ,  $c_{PS}$  with respect to the superstructure mass. This constraint is based on previous works [47] as well as on manufacturing restrictions:

$$c_{NS} \leq 1000 \text{ kNs} / \text{m} \quad (\text{Constraint 4}) \quad (32)$$

$$c_{PS} \leq 1000 \text{ kNs} / \text{m} \quad (\text{Constraint 5})$$

- vi. The nominal frequency  $f_0$  of the SBA varies in the range  $[0.1 \text{ } 5] \text{ Hz}$ , (Constraint 6).

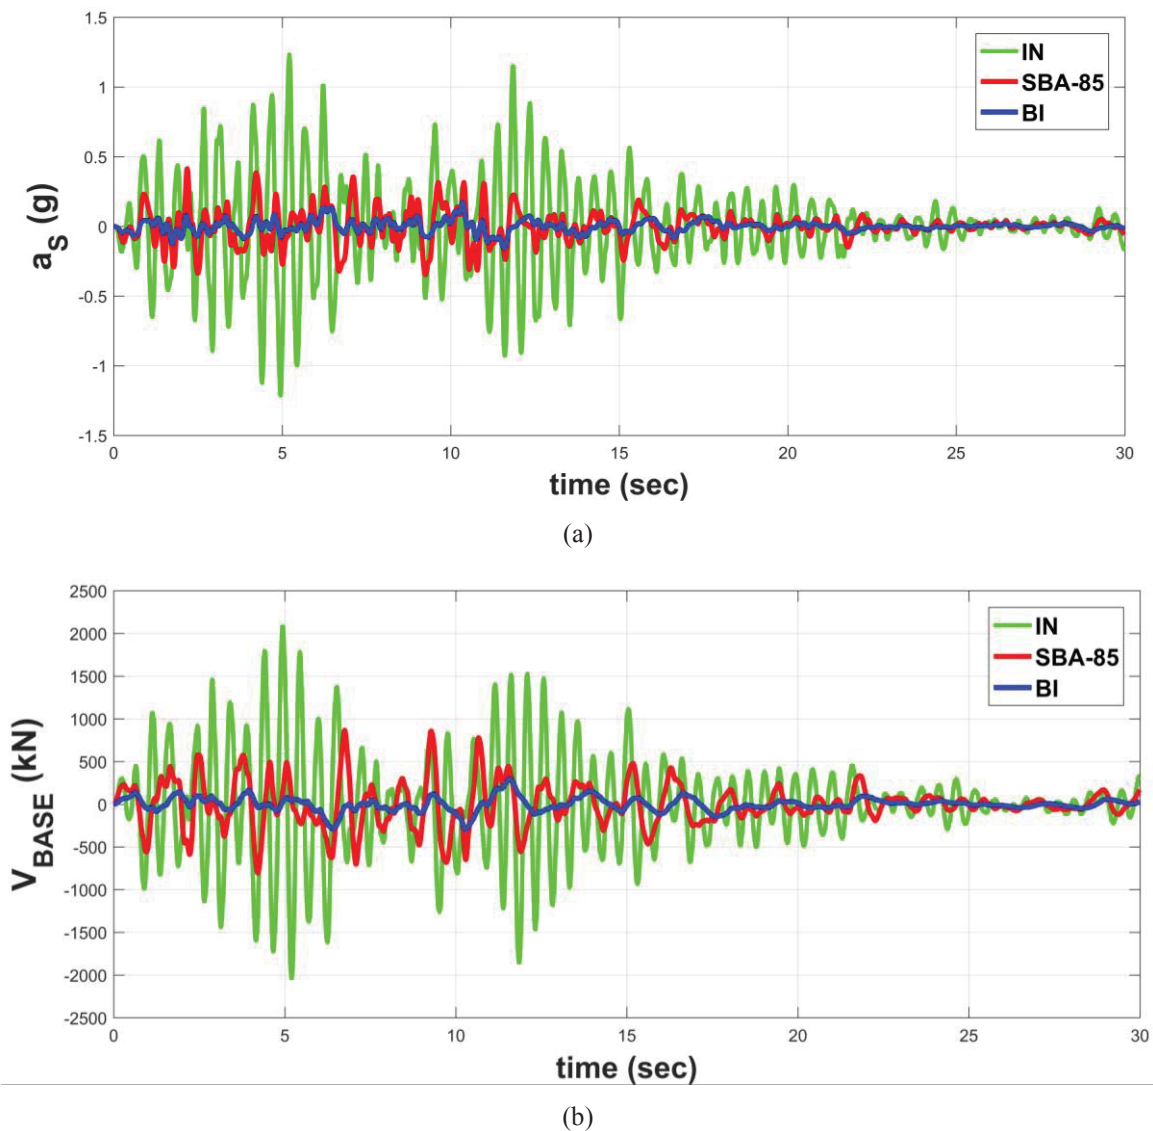

## 5 NUMERICAL APPLICATION

A numerical case study has been conducted considering a 3-story typical residential building. The elastic modulus of reinforced concrete (assuming long-term cracked conditions) is equal to  $E=26 \text{ GPa}$ . The mass of the building is considered to be concentrated at the floor levels, with  $m_i=80 \text{ tn}$  denoting the mass of each one of the 3 stories, while the columns are assumed to be weightless. Rayleigh damping is assumed (mass and stiffness proportional) with  $\zeta_{Si}=0.02$ . A  $15 \times 15 \text{ m}$  floor plan-view has been considered with  $0.3 \times 0.3 \text{ m}$  square columns. According to performed modal analysis, the natural periods of the original structure are:  $T_{Si} [\text{sec}] = [0.495, 0.177, 0.122]$ . The mass of the base is equal to  $60 \text{ tn}$  and thus the superstructure total mass is equal to  $300 \text{ tn}$ . The optimal SBA parameters obtained from the optimization procedure described in section 4.2 with acceleration filter (AF) equal to 85%, and realized with the proposed nonlinear configuration presented in section 2, are presented in Table (1).

Fix parameters		Independent design variables					Resulting stiffnesses	
$m_D$ (% $m_{tot}$ )	$\varepsilon_{NS}, \varepsilon_{PS}, \varepsilon_R$ (%)	$k_{NS}$ (kN/m)	$c_{NS}$ (kNs/m)	$c_{PS}$ (kNs/m)	$b_t$ (% $m_{tot}$ )	$f_0$ (Hz)	$k_{PS}$ (kN/m)	$k_R$ (kN/m)
5	25, 10, 10	-9000	789	667	0.135	0.808	22243	23237

Table 1: SBA set of optimized parameters for AF=70%.

In order to observe the efficiency of the proposed system, SBA, the results of the controlled structure are compared to other seismically protected structures. In particular: 1) a conventional base isolated structure with  $\zeta_B=5\%$  and  $f_B=0.4$  Hz (BI), and 2) a highly damped base isolated structure with an increased damping ratio of 20% (BI-HD). Table 2 presents the main dynamic responses of all the considered structural systems (initial, BI, BI-HD, SBA) for all the artificial accelerograms of the database (mean of max). It is observed that the SBA-85 manages to greatly improve the superstructure dynamic behavior, retaining the base displacement drastically low (few centimeters). Comparative results: a) of the top floor absolute acceleration, b) the total base shear and c) the base relative displacement between the initial, the BI and the SBA-85, are presented in Figure 7 for an artificial sample.

Figure 7: Comparative results, in terms of (a) superstructure absolute acceleration (top floor), (b) total base shear, and (c) base relative displacement between the initial, a conventional base isolated structure and the SBA-85 system implemented in the base of the structure.

		Initial	BI (5%)	BI-HD (20%)	SBA (AF=85)

### 5.1 Indicative design of the implemented SBA device

For the seismic isolation of the considered 3-story building with total mass of 300 tn, 6 SBAs are used in total, each supporting a mass of 50 tn. The devices are placed uniformly under the base of the superstructure connecting it with the foundation. In order to design the components of the SBA, the maximum dynamic responses as emerged from this section are required. Specifically, the NS element  $k_{NS}$  is designed according to the maximum NS element stroke which is  $\max|u_{NS}|=7\text{cm}$ , the PS element  $k_{PS}$  according to the maximum relative displacement of the additional mass which is  $\max|u_D|=3.38\text{cm}$  and the  $k_R$  according to the maximum relative displacement of the base, which is  $\max|u_B|=4.95\text{cm}$ .

The negative stiffness for each one of the 6 SBAs in the equilibrium position is  $k_{NSi}=-9000/6=-1500\text{kN/m}$ . Considering the values of  $k_{NSi}$ ,  $\max|u_{NS}|$ , the requirement of NS ratio to

be  $r > 0.75$  and by following the procedure described in section 2, the vertical stiffness element  $k_T$  of the NS mechanism (Figure 1) is selected to be realized with a leaf spring. The leaves of the spring along with its clips are made of steel with elastic modulus  $E=210\text{GPa}$ , shear modulus  $G=80\text{GPa}$  and yielding strength  $\sigma_y=250\text{MPa}$ . In Table 3 are summarized the parameters of the leaf spring, where  $h$ ,  $w$  and  $L$  are the dimensions of each metal leaf,  $x_T$  is the maximum deformation and  $H_S$  is the total height of the spring including the gaps between each leaf and between each group. In Figure 8 is depicted the realistic representation of the proposed spring along with its dimensions. Also, from the analysis of the NS mechanism is derived the value of the dimensionless parameter is  $c_f=0.025$  and the length of the rod is  $a=80\text{mm}$ .

Metal Leaf			Total Configuration				
$h$ (mm)	$w$ (mm)	$L$ (mm)	$N_B$	$N_G$	$k_T$ (kN/m)	$x_T$ (mm)	$H_S$ (mm)
11	760	556	5	4	1544.89	78	808

Table 3: Parameters of Leaf Spring

Figure 8: Representation of the proposed Leaf Spring (a) 3D design, (b) design drawing

For the realization of the positive stiffness elements, 4 heavy duty compression springs are implemented in each device. These types of springs are used to undergo some considerable amounts of load and are usually manufactured with large wire diameters along with the rest of its dimensions. For  $k_{PSi}=22243/(6 \times 4)=926.8\text{kN/m}$  and for maximum deformation  $\max|u_D|$  the dimensions of the each spring are summarized in Table 4. The springs are made of Hard Drawn ASTM A227 steel and have closed and squared type of ends.

Wire Diameter (mm)	Outer Diameter (mm)	Free Length (mm)	Number of active coils	Number of total coils	Solid Length (mm)	Spring Index	Pitch (mm)
30	150	300	5	7	240	4	42

Table 4: Physical dimensions of the compression spring  $k_{PSi}$ 

The artificial dampers are realized with four parallel dampers implemented per device. The damping values are low,  $c_{NS}=789/(6 \times 4)=32.875\text{ kNs/m}$  and  $c_{PS}=667/(6 \times 4)=27.8\text{ kNs/m}$ , therefore linear damping devices are used, LD1110 from ITT Infrastructure catalog. The realization of  $k_R=23237\text{ kN/m}$  is possible with 8 simple elastomeric bearings such as SI-N 500/54 ( $k_H=2910 \times 8=23280\text{ kN/m}$ ) from the FIP Industriale elastomeric isolators catalog.

## 6 CONCLUSIONS

In this paper, a stiff seismic base absorber (SBA) is proposed, that combines an extension of the KDamper concept with an inerter device, and is implemented in the base of a multi-story building for seismic protection. A novel mechanism is proposed for the realization of the NS element with leaf springs. The design of the SBA is realistic and its optimal parameters are selected based on engineering criteria. Proper constraints and limitations are posed on the independent design variables and the system nonlinear dynamic responses. The input ground motions are artificial ground motions generated to be compatible with the EC8 response spectra. In order to verify the effectiveness of the SBA, a comparison is made with a conventional and a highly damped base isolated structure. Based on the dynamic analysis and the results obtained, the following concluding remarks can be made:

1. The leaf spring is a simple, cost-efficient and robust solution to carry not only heavy vertical structural loads but also transversal forces derived by ground motions.
2. The proposed negative stiffness mechanism is capable of supporting an oscillating mass of 50tn retaining the negative stiffness ratio to acceptable levels ( $>0.75$ ).
3. The SBA is realistically designed. A small additional mass of 5% is employed, a variation in all stiffness elements is foreseen (10-25%), and the optimal system parameters are obtained by a constrained optimization procedure.
4. The superstructure dynamic behavior of the examined multi-story building controlled with SBA is greatly improved. More specifically, the floor accelerations and the inter-story drifts are significantly reduced (60-70%), and at the same time, the base displacement is dramatically low, as compared to other base isolation approaches (reductions 65-70%).
5. The design of the SBA devices is realistic and within reasonable technological capabilities.

### Abstract

*This contribution presents a multi-level optimization procedure of nonlinear viscous dampers (NVDs) for the seismic retrofit of existing substandard steel frames. The procedure is based on the concept of uniform damage distribution (UDD) and aims to identify the best characteristics of NVDs to satisfy pre-assigned design requirements. The damper-brace elements are simulated with a Maxwell model comprising a dashpot with power law force-velocity behavior in series with a linear spring simulating the stiffness of the brace-damper system. The beam and column members of the steel frames are modelled with a distributed-plasticity fiber-based section approach. The optimization procedure is based on iterative nonlinear time-history analyses performed in OpenSees interfaced with an external subroutine written in MATLAB that governs the adjustment of the damper properties. The method is developed with reference to a set of synthetic and natural earthquakes compatible with the Eurocode 8 response spectrum. The effectiveness of the design procedure is illustrated through examples on 3-, 7- and 12-storey substandard steel frames. It is demonstrated that the proposed procedure leads to frames with reduced maximum inter-story drift, maximum plastic rotation and global damage index compared to an equal-cost uniform damping distribution. A slight variant of the procedure is also capable to comply with multiple performance objectives at different intensity levels of the earthquake excitation, thus realizing a multi-level optimization of the nonlinear viscous dampers. This is of practical importance in view of current performance-based design guidelines of seismic standards.*

## 1 INTRODUCTION

Many existing structures do not comply with seismic regulations in force today and need seismic retrofitting interventions. A convenient strategy to increase the seismic performance of substandard structures while simultaneously reducing the need (and cost) of extensive interventions or localized repairing actions is to install passive energy dissipation devices [1]. These supplemental devices increase the energy dissipation capability of the structure, thus absorbing a significant portion of the earthquake input energy. In this way, the vibrational energy transferred from the ground shaking to the structure is considerably reduced, and the structure itself can remain in an elastic (or at the most quasi-elastic) range of behavior under the seismic design loads [2]. Among the most popular passive energy dissipation systems, fluid viscous dampers (FVDs) proved to be efficient devices for seismic retrofitting purposes. Some of the advantages of FVDs include the generation of velocity-dependent forces, whose peak values occur out of phase with respect to the occurrence of maximum displacements in the parent frame, and the possibility of increasing the damping features of the structure without affecting the stiffness of the structure. The latter characteristic is a major advantage compared to other hysteretic (e.g., metallic) dampers and, in general, to any displacement-dependent device as defined in the UNI EN15129 regulations. Moreover, this characteristic drastically simplifies the design procedure and the topology optimization of the devices.

The seismic performance of a structure equipped with added FVDs is reasonably affected by the choice of an appropriate size and position of the dampers. A plethora of analytical and numerical procedures for the optimal design and placement of FVDs have been proposed in the literature, as overviewed by De Domenico et al. [3], which range from sequential search algorithms [4] to gradient-based techniques [5], from evolutionary algorithms [6] to a fully stressed analysis/redesign procedure [7], stochastic-based approaches [8]-[10] or response-spectrum related procedures [11], [12]. Some of the methodologies presented in the literature assumed a simplified model of the structure (e.g., linear elastic shear-type behavior [13]) and of the FVDs (e.g., linear viscous dashpots with a force linearly proportional to the relative velocity at the two terminals [14]). Nevertheless, existing substandard frames requiring seismic retrofitting interventions may exceed the elastic threshold when subjected to severe earthquake excitations, so that incorporation of material nonlinearity in the model seems more appropriate for the correct design and optimal placement of FVDs. Additionally, the constitutive behavior of FVDs, particularly of dampers available in the market, is more faithfully described by the following nonlinear power law force-velocity expression [15]:

$$F_d = c_d |\dot{u}_d|^\alpha \operatorname{sgn}(\dot{u}_d) \quad (1)$$

where  $c_d$  is the damping coefficient;  $\dot{u}_d$  is the relative velocity between the two terminals of the device projected along the axis of the damper;  $\alpha$  is a velocity exponent related to the hydraulic circuit used, which ranges from 0.1 to 0.5 for commonly used dampers ( $\alpha=1$  for the case of linear damper);  $\operatorname{sgn}(\cdot)$  represents the signum function. For a fixed hydraulic circuit, the exponent  $\alpha$  is fixed, therefore the design of the dampers reduces to the selection of the damper size expressed by the damping coefficient  $c_d$ .

In this contribution, a multi-level optimization procedure of FVDs for the seismic retrofit of existing substandard steel frames is presented. The proposed procedure addresses nonlinear viscous dampers (NVDs) and incorporates the nonlinearity of the parent steel frame through a distributed-plasticity fiber-based section approach. The design methodology aims at achieving a state of uniform damage distribution (UDD) in the frame, thus avoiding localized damage (here quantified by the value of the inter-story drift). The state of UDD is achieved through

iterative nonlinear time-history analyses performed in OpenSees and interfaced with an external subroutine written in MATLAB that controls the adjustment of the damper properties depending on the profile of inter-story drifts at the current iteration. The proposed procedure is simple and can be applied to satisfy multiple performance objectives at different intensity levels of the seismic input, thus complying with modern performance-based design guidelines of seismic standards.

## 2 REFERENCE STEEL FRAMES AND SEISMIC INPUT

The effectiveness of the proposed design procedure is illustrated through examples on 3-, 7- and 12-storey substandard steel frames. More specifically, 3-bay planar steel frames made of steel S275 are considered, with bay width of 5.0m and story height equal to 3.2m, designed according to Eurocode 8. Dead loads and live loads equal to 5.0 and 2.5 kN/m<sup>2</sup> are considered for each story except for the roof level where the values are reduced to 3.5 and 1.0 kN/m<sup>2</sup>, respectively. For the beams, wide flange profiles (HEA types) are adopted, whereas for columns square hollow sections are used (as an example, 180x17.5 denotes a square section with thickness 17.5mm and side equal to 180mm) as listed in Table 1. Plan view and front view of a representative frame (specifically, the 7-story steel frame) are illustrated in Fig. 1.

Story level	3-story frame		7-story frame		12-story frame	
	beam	column	beam	column	beam	column
1	HE260A	180x17.5	HE300A	260x17.5	HE360A	340x17.5
2	HE260A	160x17.5	HE300A	240x17.5	HE360A	340x17.5
3	HE220A	140x17.5	HE280A	220x17.5	HE280A	340x17.5

5			HE260A	180x17.5	HE280A	340x17.5
6			HE260A	160x17.5	HE260A	320x17.5
7			HE220A	140x14.2	HE260A	280x17.5
8					HE260A	220x17.5
9					HE260A	220x17.5
10					HE260A	200x17.5
11					HE260A	160x17.5
12					HE220A	140x14.2

Table 1: Steel profiles of 3-story, 7-story, and 12-story substandard steel frames to be retrofitted with NVDs.

The finite element model of the steel frames is realized with the software OpenSees [16], using force-based *nonlinearBeamColumn* elements with five Gauss-Lobatto integration points per element, and discretizing the cross section with a number of fibers ranging from 40 to 52. Geometric nonlinearity (P-Delta effects) is incorporated in the columns, and the Rayleigh damping formulation is adopted for the steel frame (damping ratio equal to 5% is assumed for the first mode and for the mode corresponding to a cumulative participating mass equal to 95% of the total mass). The steel frames are retrofitted with NVDs mounted on diagonal braces in the central bay as depicted in Fig. 1. The NVDs are modeled in OpenSees through *twoNodeLink* elements with a *ViscousDamper* material governed by a Maxwell model (i.e., nonlinear dashpot with power law nonlinearity expressed by Eq. (1) in series with a linear spring, representing an equivalent stiffness coefficient of the damper-brace system). Throughout the examples of the paper, the exponent factor is assumed as  $\alpha = 0.3$ .

Nonlinear time-history analyses are performed under a suite of synthetic and natural spectrum-compatible records. The design response spectrum is assumed as the Eurocode 8 elastic

design spectrum with peak ground acceleration (PGA) equal to 0.4g (g being the gravity acceleration), soil type C. Fifteen natural records and six synthetic records (nomenclature SIM01 – SIM06) are selected to match the EC8 target response spectrum, as illustrated in Fig. 2 where the natural periods of the three steel frames are also marked as  $T_3, T_7, T_{12}$ .

Figure 1: Plan view (left) and front view (right) of reference 7-story steel frame (steel profiles listed in Table 1).

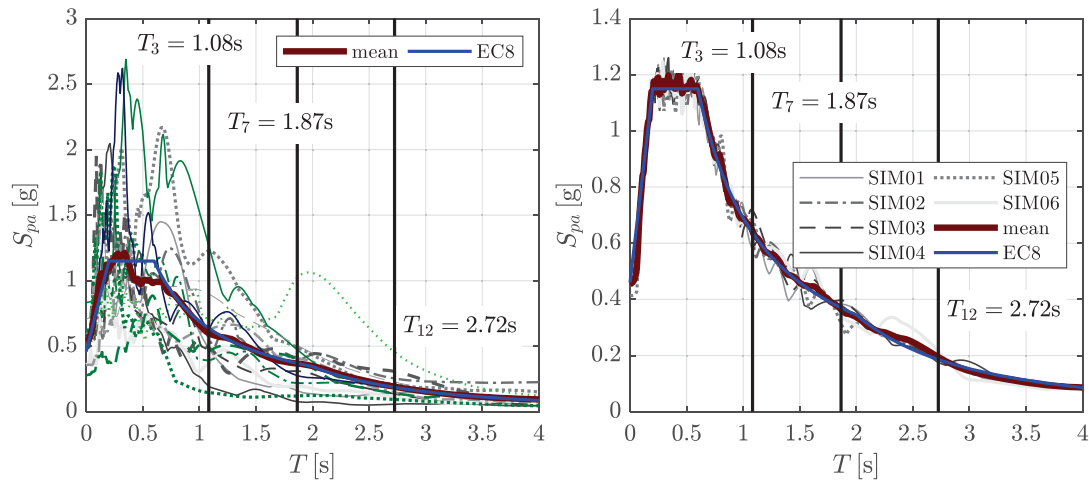

Figure 2: Acceleration response spectra of natural (left) and synthetic records (right) versus EC8 target spectrum.

### 3 UNIFORM DAMAGE DISTRIBUTION (UDD) DESIGN APPROACH

The proposed design approach aims at achieving a state of UDD in the retrofitted structure, thus avoiding localized damage. The genesis of the UDD method dates back to around fifteen years ago, and was extensively applied to performance-based optimization of different structural systems, including steel braced frames [17], truss like structures [18], shear buildings [19], reinforced concrete structures [20], [21], friction walls [22] and buckling restrained dampers [23].

To achieve the status of UDD in a structure equipped with NVDs, the damping coefficients of NVDs are increased in those story levels in which the inter-story drift (damage indicator) is higher, and are reduced in those story levels that, in contrast, are associated with a modest deformation demand (damage) according to the following sequential updating/adjustment expression:

$$c_{d,i}^{n+1} = c_{d,i}^n \times \left( \frac{\Delta_{\max,i}^n}{\Delta_{\text{target}}} \right)^\gamma \quad (2)$$

where  $c_{d,i}^n$  and  $c_{d,i}^{n+1}$  indicate the damping coefficients of NVDs at the  $i^{\text{th}}$  story level relevant to iteration  $n$  and  $n+1$ , respectively,  $\Delta_{\max,i}^n$  and  $\Delta_{\text{target}}$  represent the maximum inter-story drift ratio at the  $i^{\text{th}}$  story level calculated at the  $n^{\text{th}}$  iteration and the target value (depending on the performance requirement), respectively, while  $\gamma$  denotes a scalar parameter that affects the rate of convergence of the iterative procedure, which is assumed equal to 2.0 in this study. The sequential adjustment of the damping coefficient distribution controlled by Eq. (2) is carried on until the inter-story drift ratios tend to a uniform distribution, that is, the value of the coefficient of variation (CoV) of the inter-story drift values is lower than a fixed threshold.

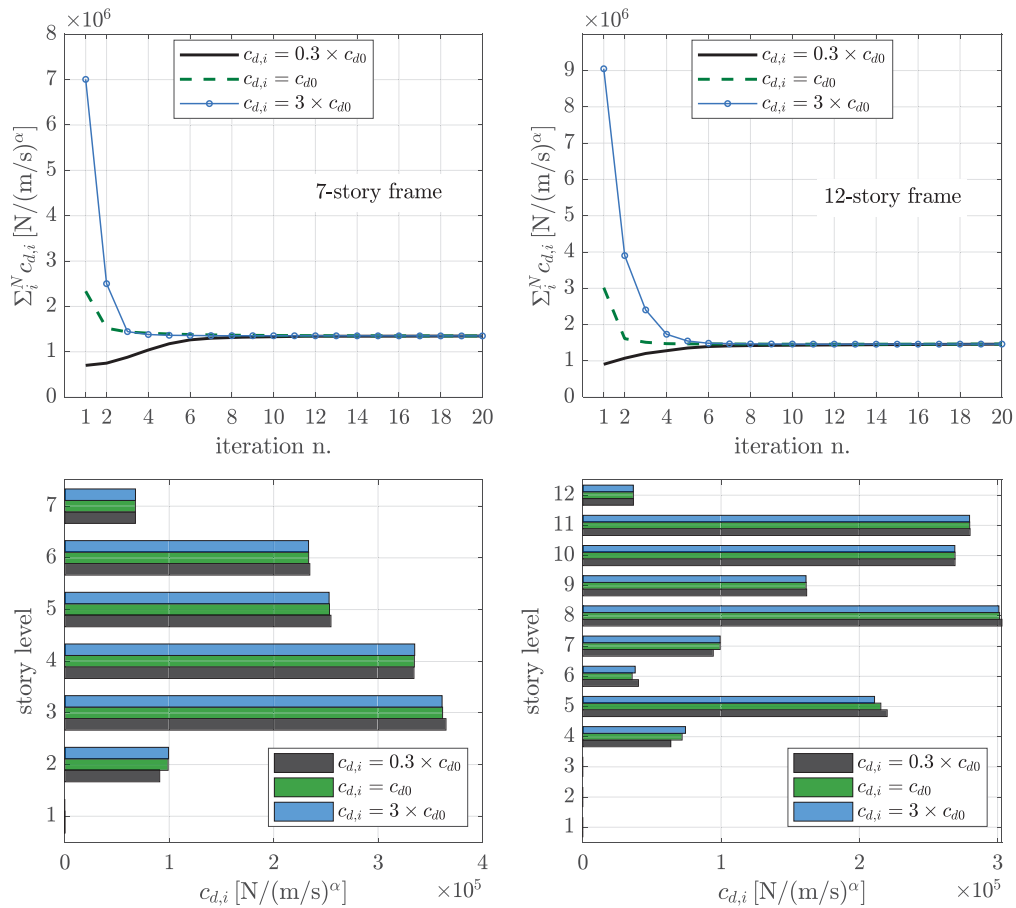

Figure 3: Effect of different initial damping distributions on convergence rate of total damping coefficient (top) and final height-wise damping distribution after 20 iterations (bottom) for 7-story and 12-story steel frames.

The application of Eq. (2) to the 7-story and 12-story is illustrated in Fig. 3 with reference to one synthetic record (SIM01). As initial step (step 0) a uniform damping distribution

$c_{d,i}^0 = c_{d0} = \text{cost}$ . is assumed, where  $c_{d0}$  is the minimum value of damping coefficient satisfying a pre-defined performance requirement (that is, the damping coefficient such that  $\Delta_{\max,i}^n \leq \Delta_{\text{target}}$  for all story levels  $i$ ). In this case, the target drift ratio is assumed as  $\Delta_{\text{target}} = 1.5\%$ , which is consistent with the FEMA life safety performance level for braced steel frames [24].

It is worth noting that assuming a different initial distribution does not lead to a local optimum solution, but to the same global solution. Indeed, to demonstrate the convergence rate and the efficiency of the proposed methodology, in addition to the uniform distribution, two alternative uniform damping distributions are analyzed as initial solutions, namely  $c_{d,i}^0 = 0.3 \times c_{d0}$  and  $c_{d,i}^0 = 3 \times c_{d0}$ . In all cases, the same final height-wise distribution of damping coefficient is obtained after 20 iterations, which confirms that the final optimum solution is basically independent from the initial choice of the damping coefficient distribution at the beginning of the sequential procedure. It is also worth noting that assuming  $\gamma = 2.0$  ensures a rapid convergence of the procedure, as the total damping coefficient tends to stabilize after just 6-8 iterations.

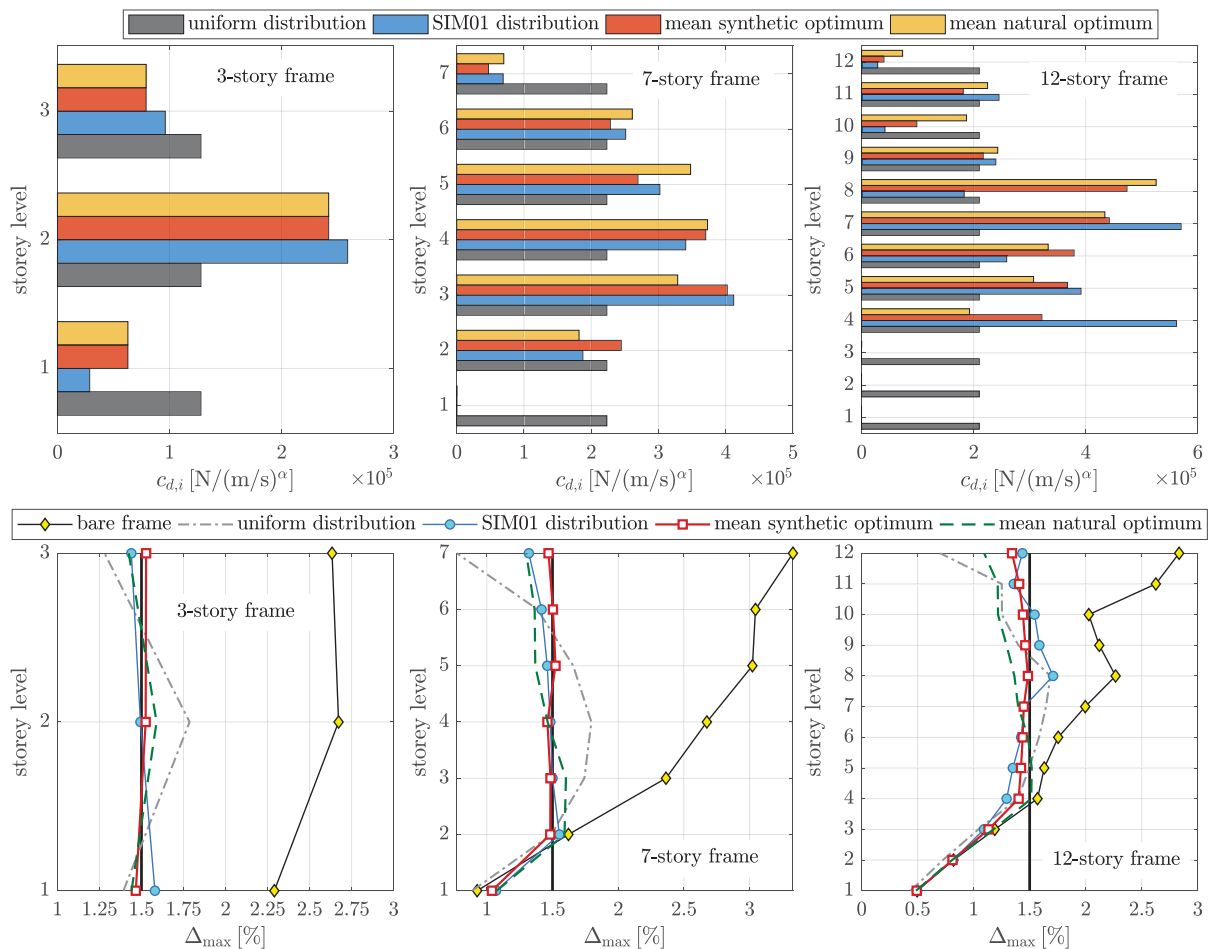

Figure 4: Comparison of four damping distributions considering different seismic input.

Another interesting point concerns the seismic input considered in the application of the proposed UDD design approach. Indeed, the optimum damping coefficient distribution is strictly related to the choice of the earthquake excitation used in the iterative nonlinear time-

history analyses. To scrutinize this effect and the sensitivity of the optimum solution to the choice of the earthquake record, in Fig. 4 four damping distributions are compared, namely: uniform distribution, UDD optimum distribution obtained by considering only the first synthetic record (SIM01 distribution), UDD optimum distribution in which the damping distribution is obtained as mean of the six distributions relevant to each of the six synthetic spectrum-compatible records (mean synthetic optimum) and of the fifteen distributions relevant to each of the fifteen natural spectrum-compatible records (mean natural optimum).

The four damping distributions compared in Fig. 4 are associated with the same total damping coefficient  $\sum c_{d,i} = \Sigma_{\text{target}}$ . This can be obtained by scaling (at each iteration) the damping distribution obtained by the iterative application of Eq. (2) according to:

$$[c_{d,i}^{n+1}]_{\text{scaled}} = c_{d,i}^{n+1} \times \left( \frac{\Sigma_{\text{target}}}{\sum_i^N c_{d,i}^{n+1}} \right) \quad (3)$$

so that the sum of the damping coefficient  $\sum c_{d,i} = \Sigma_{\text{target}}$  remains unchanged during the iterations and for every distribution analyzed. In the specific case, the value  $\Sigma_{\text{target}}$  is assumed to be that of the mean synthetic optimum distribution. The results shown in Fig. 4 demonstrate that the optimum damping distribution obtained by the proposed UDD procedure considering only one synthetic record (SIM01 distribution) represents a reasonable approximation of the optimum damping distribution obtained by considering a set of spectrum-compatible records (mean synthetic and mean natural optimum distribution). However, this is more evident in the case of 3-story and 7-story steel frames, whereas in the case of 12-story frame higher-order modes make the optimum damping distribution slightly more dependent upon the considered seismic input. In other words, the use of a single synthetic records leads to acceptable results for short-to-medium rise structures in the proposed UDD design procedure but may lead to higher approximations in the case of taller buildings.

#### 4 SEISMIC PERFORMANCE ASSESSMENT OF FRAMES EQUIPPED WITH OPTIMUM NVDS

Once the optimum damping distribution of NVDs is identified through the proposed UDD design methodology, the seismic performance can be assessed by performing nonlinear time-history analyses of the steel frames equipped with NVDs under the selected fifteen natural spectrum-compatible records. Hereafter only average max results of some selected response indicators are reported to quantify the seismic performance of the structure equipped with different distribution of NVDs, namely: NVDs uniformly distributed along the building height (called “uniform distribution”); NVDs designed according to the proposed UDD methodology considering a single synthetic record (called “SIM01 distribution”) and the mean of the damping distributions considering the six synthetic optimum distribution (simply called “optimum”). The three distributions share the same total damping coefficient, so that the different seismic performance of the three structures is uniquely related to the different height-wise distribution of the NVDs. This aims to quantify the effectiveness of the proposed UDD design philosophy against the uniform (equal cost) damping distribution in terms of seismic performance. Relevant results, in terms of average maximum values of plastic rotation, global damage index (quantified as indicated by Nabid et al. [22]), base shear and floor acceleration are depicted in Fig. 5 in a normalized fashion, scaled to bare frame results, with standard devia-

tion values being reported in the superimposed error bars. It can be observed that the proposed UDD design philosophy leads to frames with reduced maximum inter-story drift, maximum plastic rotation and global damage index compared to an equal-cost uniform damping distribution. A marked difference is noted in the values of the local (plastic rotation) and global damage indices, whereas the response in terms of base shear and floor acceleration is rather comparable in the three analyzed damping distributions, which is reasonable in view of the fact that the three damping distributions share the same total damping coefficient.

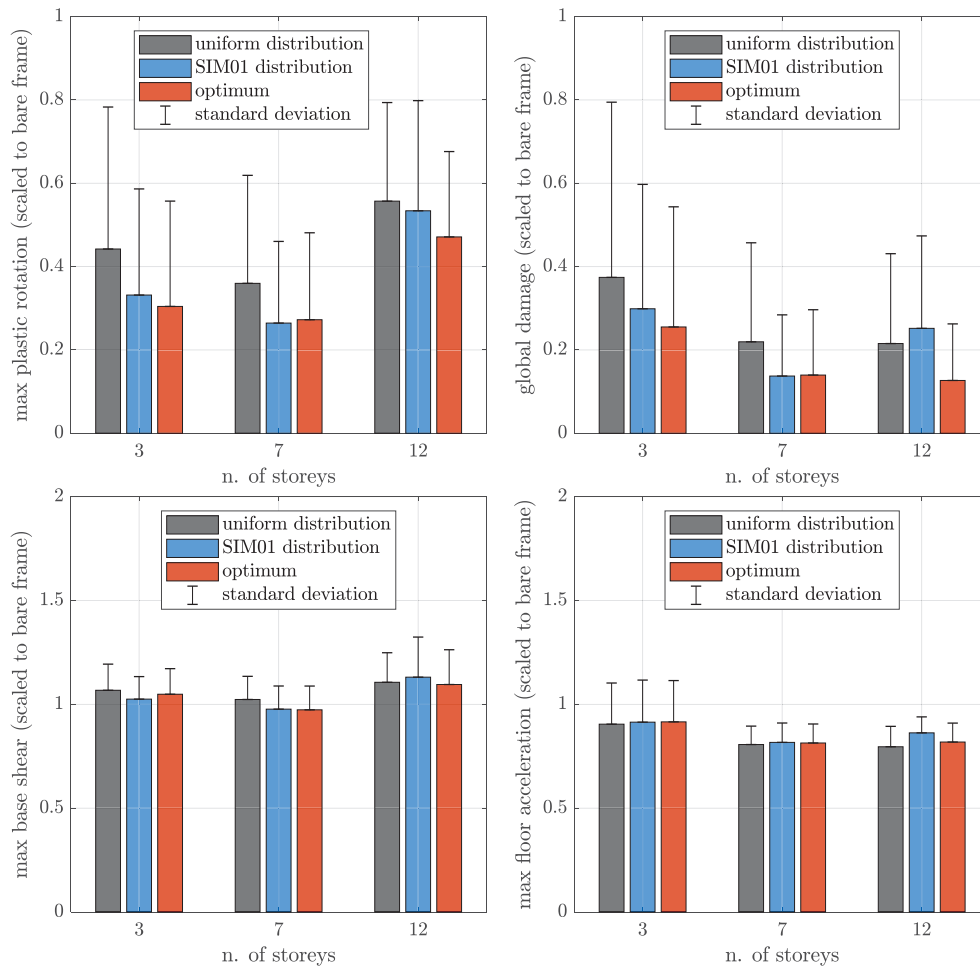

Figure 5: Seismic performance assessment of structures equipped with different distributions of NVDs.

## 5 MULTI-LEVEL PERFORMANCE-BASED OPTIMIZATION OF NVDS

It has been noted that the proposed methodology is of simple application and requires few iterations to converge. It is rather easy to incorporate the nonlinearity of the parent frame and that of the damper behavior. As an additional potential of the proposed approach, a slightly variant of the proposed UDD methodology makes it possible to address multiple performance objectives at different intensity levels of the seismic excitation. To this aim, a simple and conservative way to accomplish this objective is to generalize the sequential updating expression given in Eq. (2) as follows:

$$c_{d,i}^{n+1} = c_{d,i}^n \times \max \left[ \left( \frac{\Delta_{\max,i}^{n,I}}{\Delta_{\text{target}}^I} \right); \left( \frac{\Delta_{\max,i}^{n,II}}{\Delta_{\text{target}}^{II}} \right); \dots; \left( \frac{\Delta_{\max,i}^{n,K}}{\Delta_{\text{target}}^K} \right) \right]^\gamma \quad (4)$$

where  $\Delta_{\max,i}^{n,K}$  and  $\Delta_{\text{target}}^K$  represent the maximum and target inter-story drift ratio at the  $i^{\text{th}}$  story level, for the  $n^{\text{th}}$  iteration, and the  $K^{\text{th}}$  performance objective, respectively, with  $K = I, II, \dots$  including all the performance levels of interest.

To demonstrate the application of the proposed multi-level UDD design methodology, we extend the procedure previously illustrated for a single performance objective to two (rather than one) performance levels, namely:  $I$  = life safety (LS) performance level under the design basis earthquake (DBE) (corresponding to a 10% probability of exceedance during the reference life of the structure) and  $II$  = collapse prevention (CP) performance level under the maximum credible earthquake (MCE) (corresponding to a 2% probability of exceedance). In this paper, DBE is defined by  $\text{PGA} = 0.4g$ , whereas MCE is defined by  $\text{PGA} = 0.56g$  (that is,  $\text{MCE} = 1.4 \text{ DBE}$ ). The target inter-story drift ratio is set equal to  $\Delta_{\text{target}}^I = 1.5\%$  and  $\Delta_{\text{target}}^{II} = 2.0\%$  for DBE and MCE, in accordance with FEMA guidelines for LS and CP performance levels in braced steel frames [24].

Fig. 6 illustrates the maximum drift ratio along the building height (average results under the six synthetic records) comparing the UDD design methodology in its single-level and multi-level variant. It is clearly observed that the multi-level UDD methodology satisfies all the performance requirements on the maximum drift ratios for both DBE (LS) and MCE (CP). In contrast, the single-level UDD methodology leads to maximum drift ratios exceeding the MCE limitations for all the steel frames, in a more marked way in the case of the 3-story and 7-story steel frames, and in a less evident way for the 12-story steel frame. This example demonstrates that it is rather simple to incorporate different performance requirements in the proposed UDD design methodology through the adoption of the sequential formula (4).

Figure 6: Maximum drift ratios  $\Delta_{\max}$  for single-level and multi-level UDD design procedure under DBE-MCE.

## 6 CONCLUSIONS

A simple yet efficient performance-based methodology for the optimum design of NVDs for the seismic retrofit of existing substandard steel frames has been presented. The proposed methodology invokes a UDD design philosophy and assumes, for simplicity, that the level of damage at a specific story is directly related to the value of the drift ratio associated with that story level. However, the generality of the formulation makes it possible to address other damage-related measures in a similar fashion and using a similar implementation approach. The core of the design procedure is based on an iterative adjustment of the damping coefficients of NVDs along the building height in order to achieve a status of uniform damage. In particular, the damping coefficients of the story levels undergoing larger extent of damage are increased, whereas the damping coefficients related to those story levels experiencing modest deformation demand are decreased iteratively. The design procedure entails a sequence of nonlinear time-history analyses, performed in OpenSees, and interfaced with an external MATLAB subroutine that governs the iterative updating of the damping coefficients. The procedure is general and easily incorporates the nonlinearity of the parent steel frame (through a distributed plasticity fiber-based section approach) and of the damper behavior (through a Maxwell model comprising a linear spring in series with a nonlinear, power law, dashpot element). The efficiency of the proposed design procedure has been illustrated with reference to three benchmark structures, namely 3-story, 7-story and 12-story substandard steel frames. The convergence of the proposed procedure has been investigated with reference to the initial damping distribution (set at the beginning of the iterations) as well as by considering different natural or synthetic records (belonging to the same class of spectrum-compatible records) as representative seismic input. It has been found that the proposed UDD design philosophy leads to steel frames with reduced maximum inter-story drift, maximum plastic rotation and global damage index compared to an equal-cost uniform damping distribution. A slight variant of the procedure has also been proposed to comply with multiple performance objectives at different intensity levels of the earthquake excitation, thus realizing a multi-level optimization of the nonlinear viscous dampers, in line with current performance-based design guidelines of seismic standards.

### Abstract

*The seismic vulnerability of existing precast RC buildings not designed against seismic actions is a well-known issue nowadays, as emerged from the aftermath of the seismic events that affected many productive areas in the Emilia region (north Italy) in 2012. This is a consequence of the lack of structural redundancy and the widespread adoption of friction-based connections, which can lead to collapses and significant damage to contents. Thus, the necessity of identifying suitable intervention strategies has been widely recognized by researchers, which proposed different retrofit techniques. One of the most diffused approaches is to introduce mechanical connectors between columns and roof elements, resulting in an increase of the base shear and the need to strengthen the columns. To prevent this phenomenon, dissipative devices based on Carbon-Wrapped Steel Tubes (CWST) are introduced herein for the retrofit of existing precast RC structures, aiming at reducing the forces transmitted to columns, and providing a suitable connection between columns and beams. To this regard, this paper discusses the seismic retrofit of an existing precast building equipped with CWSTs. Linear and non-linear time history analyses have been conducted on two different models of the structure, one with hinged beam-column connections, and on the one with CWSTs. The yielding and the ultimate rotations of the plastic hinges at the base of the columns as well as the cyclic shear resistance depending on the ductility demand on each element, are defined according to Eurocode 8 prescriptions. The paper discusses the effects of the introduction of the CWSTs in the connections in terms of forces and proposes equivalent behavior factor values for the two structures.*

## 1 INTRODUCTION

Since the 1970s, precast Reinforced Concrete (RC) structures have been widely used in many countries for one-story industrial buildings such as warehouses and factories. The seismic vulnerability of existing precast RC buildings built without seismic-design criteria is a well-known issue nowadays, as highlighted by damage occurred after the 2012 Northern Italy earthquakes that affected many productive areas [1, 2, 3, 4, 5]. The main source of vulnerability of these structures is the lack of effective mechanical connectors between their structural elements, indeed friction-based connections were widespread [6, 7, 8, 9, 10]. Friction-based connections are not able to guarantee an effective shear force transmission, causing loss of support failures and collapses; moreover, the simultaneous effect of the horizontal and vertical components of the seismic action can increase the probability of occurrence of this type of failure [11]. The vulnerability of structures characterized by these frictional connections has been confirmed by numerous numerical simulations [8, 10, 12, 13, 14, 15]. In addition, the failure of beam-column connections based on friction only, can frequently occur before the development of plastic hinges at the base of columns, causing undesired non-ductile failure modes, as reported in Deyanova et al. [16].

Given the high vulnerability of friction-based connections and the economic significance of prefabricated RC structures, many strengthening solutions have been proposed in the literature [6, 8, 17, 18, 19]. The reduction of damage and collapses due to seismic events for this type of structures, becomes even more strategical since a high economic impact due to industrial business interruption has to be taken in account, in addition to the direct economic losses [20, 21, 22]. All the strengthening solutions are typically based on the introduction of steel ties, plates, or cable restraints, to avoid sliding of the beams and therefore unseating failures. Most of these solutions aim only at converting friction-based connections into hinged connections with no focus on energy dissipation, and therefore they often require the strengthening of the base of columns.

Thus, *ad hoc* solutions based on different energy dissipation mechanisms have been proposed. For instance, Dal Lago et al. [23, 24, 25] proposed to concentrate energy dissipation in simple and rather inexpensive elements, such as steel angles connectors. Scotta et al. [26] focused on the dissipative role of cladding panels acting as shear walls; Belleri et al. [27] introduced energy dissipation in hinged connection, suggesting a re-centering dissipative devices based on rotary friction; Martinelli and Mulas [28] proposed a similar solution involving the insertion of devices dissipating energy through rotary friction, with no re-centering capacity. Alternative solutions are based on the introduction of dampers, as suggested by Marinini et al. [29].

In this context, the present paper refers to a low-damage solution for the retrofit of beam-column connections of existing precast RC structures, proposing the introduction of dissipative fuse devices based on Carbon-Wrapped Steel Tubes (CWST), introduced in Pollini et al. [30, 31]. Pollini et al. [32] presented an analytical simplified approach to estimate an equivalent behavior factor to be used in design applications with these devices, validated by comparison with a large number of incremental dynamic analyses (IDAs).

In this paper, the evaluation of the improvement in the seismic behavior of an existing precast RC building retrofitted with CWST devices is proposed, through comparative considerations on the behavior factor calculated for the existing structure, and for the one after the intervention. The first part of the paper presents the properties of the dissipative fuse devices adopted for the retrofit intervention of the main frame of the building. Thus, the modelling strategies are described in detail, as well as the development of the non-linear time history analyses. Finally, the results in terms of behavior factor quantification, for the current structure and

for the retrofitted one, are proposed and discussed with the aim of evaluating the effects of the CWSTs in the reduction of the seismic vulnerability of the building.

## 2 CWST DISSIPATIVE DEVICES

The dissipative fuse devices based on CWSTs [31, 32] considered in the present paper have two main purposes: (i) to connect beam-column joints in order to prevent the possible unseating failure of beams, and (ii) to act as dissipative fuses, thus reducing the effects of seismic actions on structural elements. Specific studies in automotive engineering on structural crashworthiness [33, 34] showed that metals, combined with composite materials in thin-walled circular tubes, have excellent capacities of energy absorption under axial compressive loads. From these, the CWST devices were developed, and an example of a real application can be seen in Figure 1a.

Figure 1: (a) Example of a beam-column connection provided with coupled CWST dissipative devices; (b) single fuse device made of carbon-wrapped steel tubes.

It is worth noticing that, since each CWST (Figure 1b) dissipates energy only under compressive loading, two devices must be positioned at each beam-column joint. A threaded bar is placed through the CWSTs in order to guide their displacement, and also to ease their connection to structural elements. In this way, standard steel anchoring elements can be used to fix the threaded bar to the column. Moreover, the anchorage on the beam is guaranteed by a significantly stiff and strong steel element, able to transfer forces from beams to the CWSTs.

The CWST device works firstly in the elastic range, like a fuse restraint avoiding relative displacement between two structural components, below a certain pre-established force threshold. Above this threshold, the plastic deformation of the device begins (plasticization phase), as well as the energy dissipation.

In order to understand the behavior of the devices, in Figure 2a the force-deformation diagram of a single CWST in compression is proposed [31]. In the Figure,  $F_{eq}$  is the equivalent plastic force threshold, and  $S_{max}$  is the maximum deformation capacity. The behavior of a connection with a CWST device can be described within three main steps. In the initial branch O-A the device remains elastic, and the lateral seismic force is fully taken by the column. As soon as the force overcome  $F_{eq}$  (branch A-B of the curve), the device starts to buckle and the plastic deformation develops, while a constant value of the force is transmitted to the column. After point B, when the device attains its maximum deformation capacity, the stiffness boosts significantly. At this step, the device performs as a displacement-limiter between beams and columns,

thanks to the aforementioned threaded bar, thus, from this point, the columns fully bears the seismic load and start to deform and yield (typically at the base).

In case of ground motions, and in general under cyclic loading, the two CWSTs positioned in one joint, work alternatively. Figure 2b represents the force-deformation law of a couple of devices in case of cyclic loads. In the picture, the red path shows that, when a load reversal occurs after entering the plastic branch of one of the devices, the connection slides with no force until the recovery of the entire deformation.

Figure 2: Force-deformation behavior of the CWST device: (a) single device behavior under compression; (b) hysteretic behavior of two devices under cyclic loading.

### 3 FEM MODELS OF THE PRECAST RC FRAME

The seismic retrofit with CWST devices is herein applied to an existing precast RC building located in Carpi (MO), in the Emilia Romagna region (Italy). The building was built in the '70, and features double span main frames constituted by I-shaped precast beams, simply supported on rectangular precast columns. After the seismic events of May 2012, the building was subjected to a temporary retrofit solution with steel plates applied at the beam-column joints, aimed to prevent the unseating of the precast elements. It is worth noticing that the retrofit with CWSTs discussed in this work, has the purpose of improving the seismic behavior of the building with respect to the current condition.

The roof slab is made by simply supported hollow-clay elements, without a rigid concrete slab, thus, the structural scheme lacks structural redundancy, consisting in simply supported beams and cantilever columns [35, 36]. Since the building is simple and regular in plan, and there is not a rigid diaphragm at the roof level, the seismic behavior of the entire building can be approximated with the 2D model of one of the internal main frames, in the direction of the beams. In the orthogonal direction, a different retrofit solution was adopted.

In order to evaluate the effects of the retrofit intervention, two different frames are modelled with finite elements, with the software Midas GEN [37]:

- A) main frame of the building with hinged beam-column connections, representing the structure in the current condition with the temporary retrofit solution (Figure 3a);
- B) main frame of the building with CWST devices placed at the beam-column joints, representing the retrofitted structure (Figure 3b). In this last model, appropriate *link* elements, i.e. nonlinear springs, are used in order to model the behavior of the dissipative devices, as explained in the following sections.

The frames are subjected to seven horizontal recorded ground-motion accelerograms, according to Eurocodes prescriptions for safety verifications of existing buildings with non-linear analyses [38, 39], as furtherly described in Section 4.1. The vertical seismic action is not considered in this work.

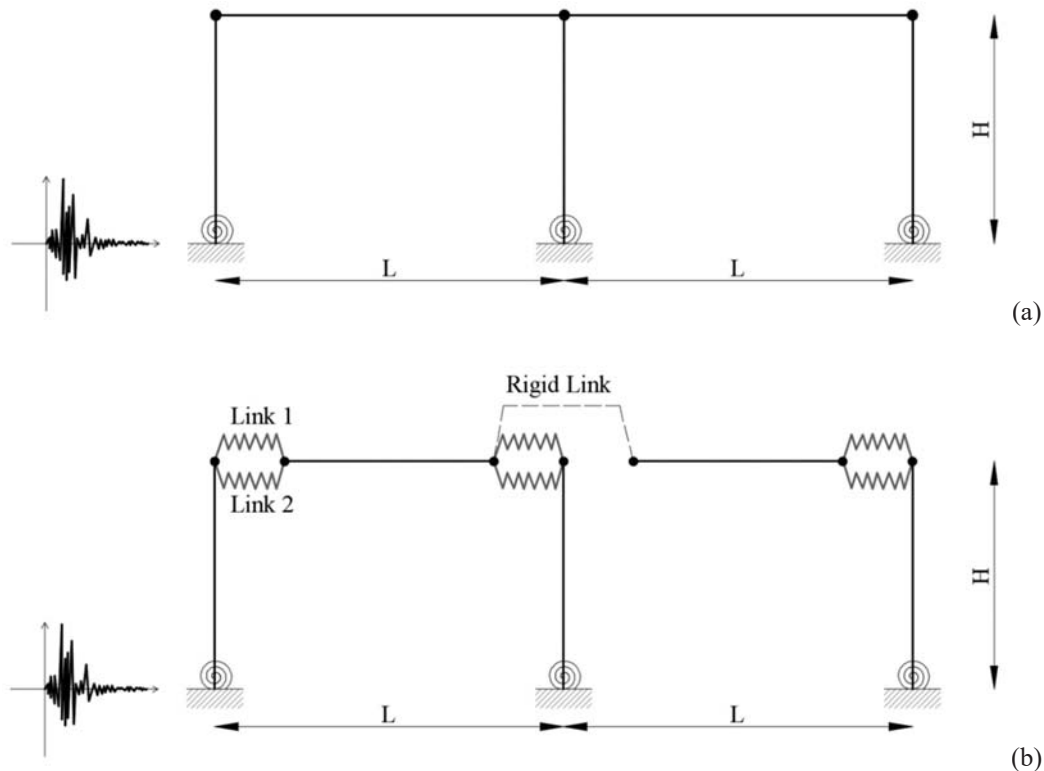

Figure 3: Structural FEM models adopted in the analyses: a) model A representing the existing structure; b) model B representing the frame retrofitted with CWSTs.

The main frame illustrated features two spans of 21.8 m, with precast main beams characterized by sections with depth spanning from 0.8 m at their ends to 1.6 m at mid-span. The three columns are 5.5 m high, with a rectangular section of 40 x 54 cm. Mechanical steel connectors are present between beams and columns, allowing to consider a rigid hinged connection between the elements in the existing condition.

The gravity loads are computed in the seismic combination of actions [38] according to the influence area of each element, and transformed into lumped masses for the dynamic analyses. The axial load ratio, computed in the seismic combination of loads, is 0.033 for the two external columns, and 0.063 for the internal. The material properties have been estimated according to in-situ testing reports, showing a concrete class C32/40 and a steel class FeB44k for the column reinforcement.

Since the building was built before the introduction of seismic design criteria in the region, the columns exhibit low seismic detailing and in particular poor transverse reinforcement. Indeed, the columns are reinforced with 4 $\Phi$ 14 ribbed bars with 2.5 cm concrete cover, and 2 additional  $\Phi$ 6 located along the height of the section, confined with transversal stirrups  $\Phi$ 6 spaced 20 cm. The columns are modelled clamped at their base, since, due to the presence of a rigid industrial floor, the interaction with the foundation is not under analysis in this work. At the base of columns, non-linear lumped plastic hinges are modelled adopting trilinear moment-rotation relationships, defined according to Eurocode 8 formulations for reinforced concrete structures [39]. The shear resistance of the columns is computed following the expression for

cyclic shear resistance calculation in Eurocode 8 [39], depending on the ductility demand of each element. It is worth noticing that, in all models, beams have a linear behavior since no damage is expected to occur in these elements.

### 3.1 Properties of the plastic hinges

The non-linear flexural behavior of columns is taken into account by means of plastic hinges at their base. Trilinear moment-rotation rules are implemented, considering the cracking point  $(\theta_{cr}, M_{cr})$ , the yielding point  $(\theta_y, M_y)$ , and the ultimate point  $(\theta_u, M_u)$ , with a perfectly plastic post-yielding behavior. The hysteresis model considered is a symmetric Takeda rule [40] able to represent the stiffness degradation of the elements, with an exponent in unloading stiffness equal to 0.4, and an inner loop unloading stiffness reduction factor equal to 1.

The value of the chord rotation at cracking is calculated as the ratio between the cracking moment and the elastic stiffness of a cantilever column with a fully reacting section. The yielding and the ultimate rotations at the life safety limit state are defined according to Biskinis and Fardis formulations [41, 42] adopted in Part 3 of Eurocode 8. The formulas are reported in Equations (1) and (2), respectively:

$$\theta_y = \phi_y \frac{L_V}{3} + 0.0013 \left( 1 + 1.5 \frac{h}{L_V} \right) + 0.13 \phi_y \frac{d_{bL} f_y}{\sqrt{f_c}} \quad (1)$$

$$\theta_{u,SLV} = \frac{3}{4} \frac{1}{\gamma_{el}} 0.016 (0.3^v) \left[ \frac{\max(0.01; \omega')}{\max(0.01; \omega)} f_c \right]^{0.225} \left( \frac{L_V}{h} \right)^{0.35} 25^{(\alpha \rho_{sx} \frac{f_{yw}}{f_c})} (1.25^{100} \rho_d) \quad (2)$$

where:  $\phi_y$  is the yield curvature at the end section,  $L_V$  is the ratio moment/shear at the end section,  $h$  is the depth of the cross-section,  $d_{bL}$  is the mean diameter of the tension reinforcement,  $f_y$  and  $f_c$  are the steel yield stress and the concrete strength, respectively,  $\gamma_{el}$  is equal to 1.5 for primary seismic elements,  $v$  is the axial load ratio,  $\omega$  and  $\omega'$  are the mechanical reinforcement ratios of the tension and compression, respectively, longitudinal reinforcements,  $\alpha$  is the confinement effectiveness factor,  $\rho_{sx}$  is the ratio of transverse steel parallel to the direction of loading,  $f_{yw}$  is the stirrup yield strength,  $\rho_d$  is the steel ratio of diagonal reinforcement, if any, in each diagonal direction. It is worth noticing that the same materials and sections characterize the three columns, which differ only because of the axial load. Mean values of the material properties are adopted to calculate moments and rotations. Moreover, the shear span  $L_V$  is equal to the full column height. The coordinates of the characteristic points of the trilinear plastic hinges are reported in Table 1.

It is important to highlight that the expression used for the calculation of  $\theta_u$  is defined for elements with ribbed bars and seismic detailing. The formula can be also adopted for elements that are not conforming to seismic codes, by applying reduction factors. In particular, empirical scaling factors are defined based on whether a member i) does not conform to modern seismic codes (22.9% reduction); ii) is not provided with properly anchored stirrups providing effective confinement (1.6% reduction); iii) has laps of longitudinal bars inside the plastic hinge region (from 15% to 66% reduction). This last factor significantly influences the calculation of the ultimate rotation [43], resulting in a reduction coefficient which increases if the lap is less than 40 diameters (in case of ribbed bars). For the case study frame, the first two empirical reduction coefficients are taken into account for the determination of  $\theta_u$ . Since the columns are prefabricated, with continuous longitudinal bars, it is not possible to consider the third correcting coefficient. All this enhances the necessity to evaluate other types of significant reduction

coefficients to be proposed in this formula for the specific case of existing prefabricated elements not designed with anti-seismic standards, for which additional research may be required [44, 45].

In this work, in order to analyse the sensitivity of the results depending on the value of ultimate chord rotation considered, the authors consider the adoption of two alternative values corresponding to 80% and 60% of  $\theta_u$ . Thus, the dynamic analyses are conducted with three different threshold values of rotations for both the models (i.e. model A and B), in order to evaluate the influence of this parameter on the estimation of the behavior factor. The values calculated for the case study frame are presented in Table 1.

	$M_{cr}$ (kNm)	$M_y$ (kNm)	$M_u$ (kNm)	$\theta_{cr}$ (rad)	$\theta_y$ (rad)	$\theta_u$ (rad)	80% $\theta_u$ (rad)	60% $\theta_u$ (rad)
External column	70.5	236.6	236.6	0.00074	0.01412	0.03232	0.02586	0.01939
Internal column	70.5	297.5	297.5	0.00074	0.01462	0.03118	0.02495	0.01871

Table 1: Characteristic points of the moment-rotation relationships adopted for the external and the internal columns of the precast frame.

### 3.2 Shear resistance

The shear in columns is checked at each step of the analysis with respect to the shear resistance, as prescribed by Eurocode 8, avoiding the modelling of non-linear shear hinges. The formula adopted for the verification is given in Eurocode 8, part 3 [39]. It accounts for the cyclic shear resistance which decreases with the increase of the plastic ductility demand  $\mu_{\Delta}^{pl}$ . This last parameter is calculated as the plastic part of the chord rotation normalized to the yielding chord rotation  $\theta_y$ . The adopted shear strength formula is reported in Equation (3).

$$V_R = \frac{1}{\gamma_{el}} \left[ \frac{h-x}{2L_V} \min(N; 0.55A_c f_c) + (1 - 0.05 \min(5; \mu_{\Delta}^{pl})) \cdot \left[ 0.16 \max(0.5; 100\rho_{tot}) \left( 1 - 0.16 \min\left(5; \frac{L_V}{h}\right) \right) \sqrt{f_c} A_c + V_W \right] \right] \quad (3)$$

where:  $\gamma_{el}$  is equal to 1.15 for primary seismic elements,  $h$  is the depth of the cross-section,  $x$  is the compression zone depth,  $L_V$  is the ratio moment/shear at the end section,  $N$  is the compressive axial force,  $A_c$  is the cross-section area,  $f_c$  is the concrete strength,  $\mu_{\Delta}^{pl}$  is the plastic part of the chord rotation normalized to the yielding chord rotation,  $\rho_{tot}$  is the total longitudinal reinforcement ratio,  $V_W$  is the contribution of transverse reinforcement to shear resistance.

In this formula, mean values of the material properties divided by the partial factors are considered to calculate the shear resistance, in accordance with Eurocode criteria for safety verifications of brittle failure modes. Moreover, the resistance is updated at each step of the analysis depending on the actual ductility demand. In addition, if the ductility demand is lower than 1, the value of shear resistance is calculated with the expression defined for members not requiring shear reinforcement, given in Eurocode 2, part 1-1 [46].

### 3.3 CWSTs dissipative devices

The CWST dissipative devices are introduced in frame B (see Figure 3), i.e. the retrofitted one. The devices are modelled in Midas GEN through the use of two *link* elements working in parallel:

- a non-linear symmetric element with property type *SLIP bilinear* (link 1 element in Figure 3b) which simulates the cyclic behavior of the devices before the attainment of

the maximum deformation capacity. A yielding strength  $F_{eq}$  equal to 30 kN and an initial stiffness is 30'000 kN/m are considered. This element works symmetrically in order to represent the presence of two CWSTs equipped at each beam-column node;

- a non-linear symmetric element with *SLIP bilinear* property defined with an initial gap of 7.5 cm (link 2 element in Figure 3b), which simulates the behavior of the devices after the attainment of the maximum deformation  $S_{max}$  capacity. It is modelled with a symmetric behavior in order to consider the maximum displacement of both tubes. The yielding strength and the stiffness of this element are set with significantly high values, so that to model a rigid hinged connection between beams and columns.

A couple of link elements with the aforementioned properties is modelled at the top of each column, connecting beams to columns, to represent a set of seismic devices working in the horizontal direction of the ground-motion. At the top of the internal column, an additional horizontal rigid link is modelled in order to connect the seismic devices to both beam ends, as shown in Figure 3. It is worth saying that a vertical support is guaranteed for each node of the beams through appropriate settings in the software.

Friction was not implemented in the models because of the uncertainty in the determination of the parameters that control this mechanism, i.e. the definition of the coefficient of friction, the combination of horizontal and vertical components of the seismic action, and the energy dissipation related to friction. Considering a frictional mechanism in the model would imply to admit the benefits of friction energy dissipation that cannot be considered to be constant, and on which it is not always possible to rely because of the variations of the axial load in columns, due to the vertical component of the ground-motion. Furthermore, standard provisions do not allow to consider friction in the seismic response of structures.

Nevertheless, the contribution of friction in terms of maximum force transferred to columns, has been taken into account in the selection of the yielding strength capacity of the dissipative devices adopted in this case study. Indeed, the value of the equivalent force of plasticization  $F_{eq}$  (see Section 2) for the CWSTs, was selected to be lower than the maximum value of force that could be transferred to the top of the columns without yielding their base sections.

Consequently, the column exhibits a certain degree of overstrength in order to guarantee that the sum of friction threshold force and of forces transmitted by the CWST devices, is lower than the force that would lead to the formation of a plastic hinge at the base. This is in accordance with the design criterion of this retrofit intervention, aimed at having columns performing linear elastic until the devices reach their maximum deformation capacity. Therefore,  $F_{eq}$  plus the contribution of frictional forces, has to be lower than the force activating yielding in columns, i.e. about 43 kN in for the external columns, and 54 kN for the central column, for the frame under analysis.

#### 4 TIME-HISTORY ANALYSES

The first step of this Section consists in performing linear modal analysis to estimate the first period of vibration of the existing frame. For this purpose, model A is implemented in a linear model without the three plastic hinges at the base of the columns, but considering the cracked stiffness of the columns, following Eurocode 8 prescriptions [38]. In particular, a reduction coefficient for the moment of inertia of each column has been evaluated, so that to consider the secant lateral stiffness at yielding of each column. The result of this analysis is a first period of vibration  $T_1$  of 1.561 seconds, for which almost the entire modal mass of the structure is participating. Indeed, precast RC structures are typically simple and strongly dominated by one vibrating mode [31].

#### 4.1 Selection of the records

The seismic input adopted for the non-linear dynamic analyses is a set of 7 spectrum-compatible ground acceleration time histories. The target spectrum for the selection is the life safety limit state elastic response spectrum, defined by the Italian building code [47] for the site of Carpi (MO) in Italy. This spectrum has a return period of 712 years, corresponding, to a nominal life equal to 50 years and importance class III. Ground type C with no topographic amplification effects is assumed. The 7 accelerograms used in the analyses were selected from the NGA-West database developed by PEER [48], with the following *ad hoc* algorithm: i) only earthquakes with moment magnitude between 4 and 6 and recording stations with source-to-site shorter than 30 km are considered; ii) pulse-like ground-motions are excluded; iii) recordings not usable for periods up to 3.0 s are excluded [49]; iv) all spectra of the remaining accelerograms are scaled to the PGA of the target spectrum; v) response spectra with scaling factors higher than 3.0 or lower than 0.4 are excluded; vi) the scaled spectra are sorted based on ascending values of the average root-mean-square deviation of the observed spectrum from the target (DRMS) [49] in a range of periods from 1.0 s to 3.0 s; vii) all the possible combinations of 7 spectra are considered among the 10 scaled spectra with the lowest DRMS values; viii) for each combination of 7 spectra the DRMS value for the mean spectrum is computed; ix) the 7 spectra with the mean spectrum with the lowest DRMS value are identified.

The selected scaled spectra are plotted in Figure 4, and the corresponding ground-motion data are reported in Table 2. In particular, the earthquake name and year are indicated, together with the name of the recording station, the Joyner-Boore source-to-site distance  $R_{JB}$ , the moment magnitude ( $M_w$ ), the direction of the horizontal component with reference to the NGA classification [48], the peak ground acceleration PGA, and the scaling factor  $SF^0$ .

Following Eurocode 8 recommendations [38] when seven ground motions are used, the average result of the response quantities from the analyses is adopted to compute the value of the action effect.

Figure 4: Scaled response rectum for each of the 7 accelerograms selected (gray lines), average spectrum (red), and target code spectrum for spectral compatibility in the range of periods spanning from 1.0 s to 3.0 s. The PGA is indicated with the symbol  $\times$ . All the accelerograms are scaled to the same PGA.

N°	Earthquake name, Year [-]	Station name [-]	$R_{JB}$ distance [km]	$M_w$ [-]	Component [-]	PGA [m/s <sup>2</sup> ]	SF <sup>0</sup> [-]

#### 4.2 Non-linear analyses

Non-linear time history analyses have been performed on both model A (frame with hinged connections) and model B (frame retrofitted with CWSTs), with the purpose of estimating, for each accelerogram, the scaling factor that leads to the attainment of one of the ultimate conditions of the structure. In particular, each record is gradually scaled until one of these collapse conditions is reached: (i) ultimate chord rotation in one of the three columns; (ii) cyclic shear resistance in one of the three columns. It is worth saying that the scaling of the time-histories is performed with factors SF<sup>1</sup> on the records already scaled with the SF<sup>0</sup> introduced for the spectra compatibility. The scaling factors SF<sup>1</sup> are reported up to the first decimal digit. Therefore, the  $i$ -th accelerogram is actually scaled by  $SF_i = SF_i^0 \cdot SF_i^1$ .

The non-linear analyses are carried out with Rayleigh damping, calculated based on the first and the second periods of vibration (see Section 4.1), considering 5% damping ratio. P-Delta effects are also taken into account in the analyses, even if not particularly significant for this frame, since the columns are characterized by low axial loads.

For each analysis, the time histories of the following response parameters are evaluated: the shear in columns, the displacements at the top of columns, the chord rotations of columns, the hysteretic behavior of the CWSTs and of the plastic hinges. As mentioned before, the analyses are conducted considering three different values of the ultimate chord rotations:

- Rotation Limit RL1 - Ultimate chord rotations calculated with Equation (2);
- Rotation Limit RL2 - 80% of the values of the ultimate chord rotations adopted in RL1;
- Rotation Limit RL3 - 60% of the values of the ultimate chord rotations adopted in RL1.

As an example, some significant results are proposed for models A and B, referring to the accelerogram TH6, for a scaling factor SF<sup>1</sup> equal to 1, for the ultimate chord rotations capacity RL1. Figure 5 shows moment-rotation plots for the left and the central column of the frame, for the model A (black line) and the model B (red line). In the model A, the rotation in all plastic hinges exceeds the yielding point, while in the model B, all columns remain elastic. Moreover, in model B, one of the CWST devices in each couple at the top of the three columns, reaches the maximum deformation capacity  $S_{max}$ . Therefore, the three link 2 elements (see Section 3.3) are activated, transferring the full effect of seismic actions from beams to columns. This effect is visible in Figure 6, which shows the non-linear force-deformation cyclic behaviors of the three devices in model B. The cyclic behavior link 1 elements are shown in Figure 6a, these have a deformation capacity  $S_{max}$  equal to 7.5 cm, then the link 2 elements are activated (Figure 6b).

With the subsequent increase of the scaling factor SF<sup>1</sup> of time history TH6, the yielding of the plastic hinges of columns gradually occurs also in model B. However, the three columns in

model A reach the ultimate rotation values for a  $SF^1$  equal to 1.30, lower than the one corresponding to model B, which is equal to 1.70. Furthermore, for all time histories, it can be observed that the plastic hinges of the columns in model B remain elastic until the CWST devices attain their ultimate deformation capacity. This confirms that the CWSTs in model B, allow to guarantee a higher performance against the ultimate rotation capacity of columns.

Figure 5: Cyclic behavior of columns plastic hinges for model A (black line) and model B (red line), for time history TH6 and  $SF^1 = 1$ : a) left column the frame; b) central column of the frame.

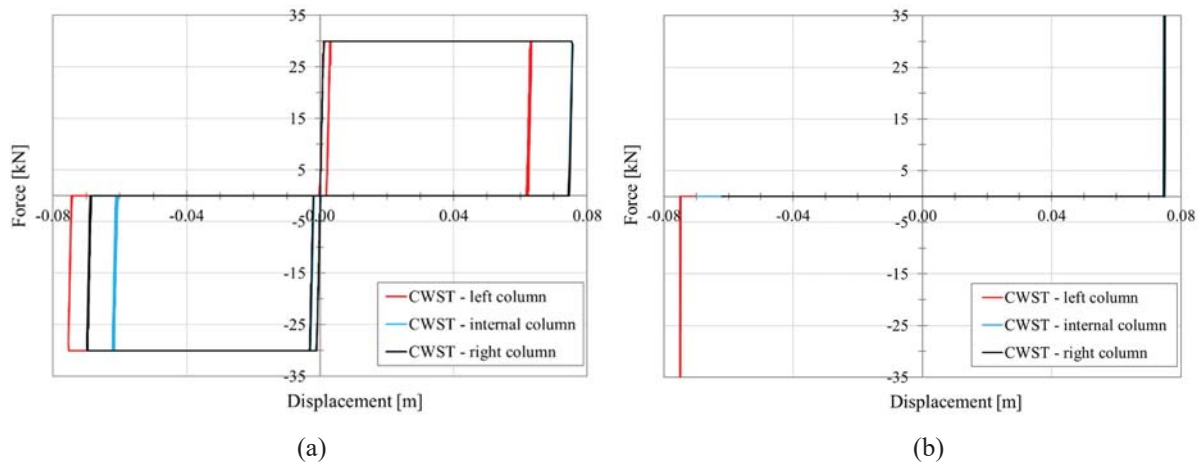

Figure 6: Cyclic behavior of the three CWSTs at the beam-column nodes in model B, for time history TH6 and  $SF^1 = 1$ : a) cyclic behavior of link 1 (see Section 3.3); b) cyclic behavior of link 2 (see Section 3.3).

In order to further evaluate the influence of the CWSTs, the time-histories of the deformations in the plastic hinge, and the shear in the left column of the frame, are proposed in Figure 7 and 8, for the accelerogram TH2 and the rotation limit RL1. Figure 7a and 8a refer to a scaling factor  $SF^1 = 1.5$  for both models, while Figure 7b and 8b refer to a scaling factor  $SF^1 = 2$ . In Figure 7, the positive effect of the devices can be observed in terms of lower deformations in model B compared to model A. Figure 8a shows that the left column in model A reaches a value of shear that corresponds to the yielding of the plastic hinge (about 43 kN), while the left column in model B has lower shear values. Indeed, for a scaling factor  $SF^1 = 1.5$ , all the columns in model A are yielded, while all the columns in model B are still elastic.

Figure 7: Time-histories of the chord rotation of the left column for TH2, for model A (black line) and model B (red line): a)  $SF^I = 1.5$ ; b)  $SF^I = 2.0$ .

Figure 8: Time-histories of the base shear for the left column for TH2, for model A (black line) and model B (red line): a)  $SF^I = 1.5$ ; b)  $SF^I = 2.0$ .

For  $SF^I = 2$ , Figure 8b, it is possible to observe that the left column reaches the yielding force both in model A and B. However, in Figure 7b it can be noticed that, even if the left column is yielded in both models, the deformation of the plastic hinge in model B is lower than in model A. This is the positive effect of the activation of the CWSTs in the non-linear model B.

As mentioned before, the different values of chord rotations influence also the calculation of the resistance against cyclic shear. For the left column of the frame with  $SF^I = 2$ , that is equal to 82.3 kN for model A and 135.7 kN for model B. Whereas, for  $SF^I = 1.5$ , they decrease to 80.6 kN and 81.7 kN, respectively. Indeed, due to the fact that the ductility demand is higher in model A, the shear resistance is lower than the one found for model B, for both scaling factors. In any case, the shear strength of columns is always higher than the shear value corresponding to the maximum flexural capacity of the plastic hinges, therefore no shear failure is predicted by the analyses. Therefore, the base shear at the ultimate condition is equal for systems with and without CWSTs, so the verifications depend on the value of chord rotations only.

Table 3 summarizes the scaling factors to be used in models A and B in order to achieve the ultimate rotation of the plastic hinges at the base of columns, considering the three different rotation limits RL defined at the beginning of the present section. The positive effect of the CWSTs is generally visible, since the model B reaches the collapse condition for higher scaling factors compared to model A. However, ground-motion record TH1 has an opposite behavior for the rotation limit RL1. Anyway, this effect is not observed considering all the other cases.

This particular behavior can be attributed to the insurgence of dynamic amplifying effects in model B for this specific record, at scaling factors  $SF^1$  higher than 2.8. Indeed, for lower scaling factors, the positive action of the CWSTs is again evident in model B. As expected, the lowest scaling factors for both models A and B among the three thresholds considered, are found for RL3, corresponding to 60% reduction of the ultimate chord rotations.

N°	$SF^0$	RL1: $\theta_u$		RL2: 80% $\theta_u$		RL3: 60% $\theta_u$

## 5 BEHAVIOR FACTOR ESTIMATION

The evaluation of the behavior factor for the existing structure (Model A), and for the structure equipped with CWSTs (Model B), is discussed out in this section. The behavior factor  $q$  is calculated as:

$$q = \frac{V_{b,el}}{V_{b,nl}} \quad (4)$$

where  $V_{b,nl}$  is the maximum base shear calculated from the non-linear analyses described in Section 4.2, with a ground-motion scaling factor bringing each model to the ultimate chord rotation, and  $V_{b,el}$  is the maximum base shear in an equivalent elastic structure with the same base acceleration. For all the limits of ultimate chord rotation considered,  $V_{b,nl}$  is constant and equal to 140 kN while the corresponding scaling factor for each accelerogram is reported in Table 3, with reference to the three different rotation limits RL. The absolute values of  $V_{b,el}$  obtained from the equivalent elastic model are reported Table 4. This model is similar to model A, but it does not have plastic hinges at the base of columns.

N°	$V_{b,nl}$ [kN]	RL1: $\theta_u$		RL2: 80% $\theta_u$		RL3: 60% $\theta_u$	
		$V_{b,el}$ [kN]	$V_{b,el}$ [kN]	$V_{b,el}$ [kN]	$V_{b,el}$ [kN]	$V_{b,el}$ [kN]	$V_{b,el}$ [kN]
		model A	model B	model A	model B	model A	model B
TH1	140	483	441	412	427	309	354
TH2	140	493	558	427	493	289	359
TH3	140	375	466	328	421	257	281
TH4	140	440	591	395	506	258	350
TH5	140	318	528	267	401	197	318
TH6	140	371	471	318	422	263	371
TH7	140	341	543	289	460	234	341

Table 4: Absolute values of the base shear calculated in the time-history analyses of the linear frame model. See Table 3 for the corresponding scaling factors for the accelerograms.

As an example, the time histories of the base shear for the equivalent linear model are reported in Figure 9, for TH7. In particular, Figure 9a concerns RL1 and shows with a black line the base shear  $V_{b,el}$ , calculated with a scaling factor  $SF^1 = 3.6$  obtained from model A, and with a red line  $V_{b,el}$  calculated with  $SF^1 = 6.2$ , obtained from model B. The value of  $V_{b,nl}$  is also reported with a dashed line. Clearly, since the model is fully linear, the time histories are simply scaled. Figure 9b illustrates the same results for RL3, corresponding to the 60% reduction of the ultimate chord rotation thresholds. The plots correspond to  $SF^1 = 2.4$  for frame A, and  $SF^1 = 3.6$  for frame B. In this case, with a lower threshold for the ultimate condition compared to the previously discussed case, the gap between the results of frames A and B is lower. This is probably due to the aforementioned amplifying dynamic effects observed at higher values of the scaling factors.

Figure 9: Time-histories of the base shear  $V_{b,el}$  for record TH7, for model A (black line) and model B (red line): a) results for RL1 with threshold  $\theta_u$ ; b) results for RL3 with threshold 60%  $\theta_u$ .

Table 5 reports the behavior factor values calculated with Equation (4) for each RL, and the corresponding average values in the bottom row. The same values are plotted in Figure 10, showing the variability of  $q$  for the seven accelerograms adopted, for each model. On average, the variability of  $q$  is consistent with the values observed for the precast buildings analyzed in Pollini et al. [32].

It is worth noticing that the same behavior factors are obtained for TH5, TH6 and TH7, both for model A for RL1, and for model B for RL3. These results for the two models are not correlated, and they are probably due to the fact the scaling factors  $SF^1$  are calculated up to the first decimal digit. If additional analyses were performed, considering more refined scaling factors, the results would likely differ for the two models.

As expected, the adoption of different ultimate chord rotations in columns affect significantly the results, since in RL2 and RL3 there is a consistent reduction in the behavior factors with respect to RL1. In particular for what concerns the model A, the average behavior factors for RL2 and 3 are 14% and 36% lower than the value obtained for RL1, respectively. Similarly for the model B, the behavior factors are 13% and 34% smaller compared to RL1 results.

Eurocode 8 part 1 [38], would recommend to adopt a behavior factor lower than 1.5 for a newly designed precast structure without seismic detailing. Moreover, Eurocode 8 part 3 [39] suggests to adopt a behavior factor not higher than 1.5 for an existing reinforced concrete structure for which the available ductility is not specifically justified. Since the columns of the existing frame under analysis are characterized by poor transversal reinforcement and are not designed against seismic actions, the average behavior factor of 2.88 obtained for model A is

deemed to have a certain degree of overestimation. The result is considered to be more realistic for this case study, when a reduction of the ultimate chord rotation is introduced. In particular,  $q$  decreases from 2.88, to 2.49 with a collapse limit 80% of  $\theta_u$ , and to 1.84 with a collapse limit 60% of  $\theta_u$ . These results clearly depend on the ultimate rotation limits predicted by Equation (2), which are not specific for existing precast columns, therefore, additional research is necessary in order to find more suitable formulations to be applied to this structural typologies, as recognized also by Magliulo et al. [45].

## 6 CONCLUSIONS

The paper discusses the seismic retrofit of an existing precast RC building equipped with CWSTs at beam-column joints. Non-linear time-history analyses have been conducted on two different models of the main frame of the structure, one with hinged beam-column connections representing the existing condition (model A), and on the one with CWST devices (model B). The effects of the introduction of the CWSTs in the connections is evaluated in terms of chord rotations demand on the columns and base shear forces, and equivalent behavior factors are proposed for the two structures. The sensitivity of the outcomes depending on the ultimate

chord rotations of columns is analyzed considering three rotation limits. On the basis of the results of the numerical simulations, the following conclusions can be drawn:

- In general, the maximum chord rotations of columns observed in the frame model with CWSTs are lower than the maximum values observed in the frame model with hinged connections, at the same scaling factor of the records, i.e. under the same seismic action;
- The damage mechanism of columns is in fully agreement with the design criteria adopted for the intervention, since, in all the analyses, the columns in model B do not yield until the attainment of the maximum deformation of the devices;
- Equivalent behavior factors are calculated for model A and model B, for three threshold values of ultimate chord rotations;
- The behavior factors estimated for model B are always higher than the ones estimated for model A, featuring simple hinged connections: the increase of the mean values of behavior factor is about 30% for model B with dissipative devices;
- The behavior factor depends on the ultimate chord rotation of columns considered, showing that the behavior factor significantly decreases with the decrease of  $\theta_u$ ;
- Additional analyses adopting other formulations for the calculation of  $\theta_u$  are required in order to find realistic results for the specific case of evaluating existing precast columns; moreover, further research may be necessary for the modelling of the non-linear flexural behavior of precast elements;
- CWST devices are deemed to be a good solution for maintaining a low level of stress and deformation in the existing columns of the frame, since frame model B is less vulnerable than frame model A, under the same seismic actions.

### Abstract

*Damage incurred in low-ductility reinforced concrete (RC) buildings during recent earthquakes continues to underline their structural vulnerability under seismic shaking. Among the viable seismic retrofitting procedures, passive control systems such as buckling-restrained braces (BRBs) have emerged as an efficient strategy for structural damage mitigation through stable energy dissipation while providing additional strength and stiffness to low-ductility buildings. Although quantifying the beneficial effects of BRBs for vulnerability reduction through seismic fragility curves has been suitably investigated in literature, almost all such studies consider a deterministic description of the BRB device. This study illustrates a meta-modeling framework rooted in statistical learning techniques for efficient seismic vulnerability assessment of BRB-retrofitted low-ductility RC frames. The framework develops multidimensional probabilistic seismic demand models for response prediction of a case study retrofitted frames as a function of ground motion characteristics as well as the design parameters of the BRB device. These demand models when compared against damage states capacity estimates subsequently yields vector-based seismic fragility functions that provide notable advantages over unidimensional fragility curves in terms of efficiency as well as generality. Additionally, uncertainties stemming from a multitude of sources can also be conveniently captured and propagated through the different stages of statistical model development. The proposed study aims to help researchers, stakeholders, and even device manufactures by providing a convenient tool for vulnerability evaluation of retrofitted structures with reasonable accuracy and enhanced efficiency of computation.*

## 1 INTRODUCTION

Many recent earthquakes worldwide have continued to underline the substantial seismic vulnerability of existing reinforced concrete (RC) buildings (*e.g.*, [1][2]) and the urgent need for reliable retrofit strategies to effectively increase their seismic safety and resilience.

Among the many retrofit strategies available, the use of passive control systems [3] such as buckling-restrained braces (BRBs) have emerged as an efficient strategy for structural damage mitigation through stable energy dissipation while providing additional strength and stiffness to low-ductility buildings (*e.g.*, [4][5][7][6][8][9][10]). BRBs are a type of yielding device where a sleeve provides buckling resistance to an unbonded core that resists the axial stress. As buckling is prevented, the BRB's core can develop axial yielding in both tension as well as compression, with an almost symmetric hysteretic behaviour and the development of large and stable hysteretic loops, providing significant energy dissipation capacity [11].

The use of BRBs for seismic retrofitting has been widely investigated in the last few years, however, while the effect of some uncertain parameters, such as the ground motion record-to-record variability, is often investigated (*e.g.*, [7][8][10]), only a deterministic description of the dampers' properties is usually considered.

The seismic reliability assessment of a structural system should consider all the uncertainties related to the seismic input, the geometry, the mechanical properties of the structure, as well as the dissipative devices contributing to the lateral load resisting system. Previous studies have shown that, in conventional structures, the effect of model parameter uncertainty is usually negligible with respect to the record-to-record variability [12]; however, this is not the case for structures equipped with dampers since their seismic response heavily depends on the properties of a few numbers of devices (*e.g.*, [13][14][15][16]).

Dampers are produced by the manufacturer in order to meet the design values of some parameters and successively assessed by quality-control tests considering tolerance limits established by seismic and qualification codes (*e.g.*, [17][18][19]). Codes worldwide provide varying tolerance limits for different types of devices, considering different device properties and the influence of multiple factors, such as, imperfections related to the manufacturing process, temperature variation, and aging. For example, the EN 15129 [17] requires the control of the devices' variation with respect to the nominal values introducing upper and lower limits of the devices' properties, defined by a tolerance. For 'displacement dependent devices', such as BRBs, the EN 15129 [17] requires performing qualification tests to show that the effective (*i.e.*, secant) stiffness  $K_{eff,b}$ , and effective damping  $\xi_{eff,b}$  evaluated in correspondence to the design displacement are in good agreement with the prescribed nominal design values. Tolerances are set to  $\pm 15\%$  to account for variation during the manufacturing process. These two control parameters ( $K_{eff,b}$  and  $\xi_{eff,b}$ ) exhaustively identify the primary characteristics of the device behaviour. Therefore, the code-based tolerance limits are also implicitly applied to other related parameters, such as the associated device forces and displacement capacity values. Similar recommendations exist within the ASCE/SEI 7-16 [18] and other seismic codes worldwide. In particular, the ASCE/SEI 7-16 [18] allows for tolerances that could go up to  $\pm 20\%$  from nominal design values and controlling the variation in terms of device's force  $F_b$  and area of the hysteretic loop  $E_{loop,b}$  measured during the tests wherein the latter parameter allows the control dissipation capacity variation of the devices.

In a recent study, Freddi *et al.* [16] investigated the influence of the BRBs' uncertainty related to tolerance limits used in device qualification control tests by considering a three-story three-bay RC moment-resisting frame (MRF) as case study. BRBs' uncertainty was implemented through a two-level factorial design strategy and Latin-Hypercube Sampling technique. Cloud analysis and probabilistic seismic demand models were used to develop fragility

functions for the bare and retrofitted frame for four damage states while also accounting for the uncertainty in the property of BRBs. Risk estimates were successively evaluated for three case-study regions. The results showed that, for the considered case-study structure, these uncertainties could lead to an increase of fragility up to 21% and a variation in seismic risk estimates up to 56%. The obtained results underlined the impact of the BRBs' uncertainty and the need for appropriate safety coefficients for their design as functions of the tolerance limits adopted. Also, additional studies are required to investigate the influence of BRB device variability on different case study structures, considering different retrofit levels (*i.e.*, different proportions of the base shear between the MRF and the BRBs) and the influence of different tolerance limits. This would require modelling a large number of case study structures and performing a large number of numerical analysis while considering the influence of all the above-mentioned parameters.

However, advanced probabilistic tools allow the study of the influence several parameters in a simplified and efficient way. In this direction, the present study investigates the use of a metamodeling framework rooted in statistical learning techniques for efficient seismic vulnerability assessment of BRB-retrofitted low-ductility RC frames accounting for different tolerance limits adopted during qualification tests of BRB devices. The framework develops multidimensional probabilistic seismic demand models for response prediction of a case study retrofitted frames as a function of: a) ground motion characteristics, and b) design parameters of the BRB device. These demand models when compared against damage states capacity estimates subsequently yields vector-based seismic fragility functions that provide notable advantages over unidimensional fragility curves in terms of efficiency as well as generality. The present study demonstrates the adequacy of such advanced probabilistic tool for vulnerability evaluation of retrofitted structures with reasonable accuracy and enhanced efficiency of computation and establishes a framework for the inclusion of uncertainties stemming from additional sources.

## 2 CASE-STUDY RETROFITTED LOW-DUCTILITY FRAME

### 2.1 Frame Description

The present study selects a benchmark three-story three-bays RC MRF, representative of non-seismically designed (low-ductility) low-rise RC buildings. This structure is representative of typical constructions designed before the introduction of modern seismic design codes in several areas of the mid-west of the USA, many countries in Europe, and several regions in Asia. Moreover, the availability of laboratory experimental test results from a 1:3 reduced scale model of the case-study frame [20], as well as frame-subassemblages [21], makes the selected reference structure as an ideal choice for this study. FE model validation against experimental results helps in gaining confidence in the numerical approach as well as predicted building response at both the global- and local-level.

Figure 1 shows the frame layout including the placement of the BRBs. The dissipative braces (BRBs) employed in RC MRFs are typically made by a series arrangement the BRB device and an elastic steel brace exhibiting adequate over-strength (see Figure 1). The case-study frame has an inter-story height of 3.66 m, a total building height of 10.75 m, and constant bay width of 5.49 m. The building is designed for gravity loads only, without any seismic detailing provisions following the pre-seismic design rules of the ACI 318-89 [22]. Furthermore, negligible wind loads for low-rise structures, such as the case-study frame, leads to a complete lack of accounting for lateral loads in the frame design. The building columns are constant square sections of 300 mm  $\times$  300 mm, while beams dimensions are 230 mm  $\times$  460 mm at each floor. The concrete compressive cube strength is  $f_c = 24$  MPa, and the reinforcing bars are Grade 40 steel with a yield strength of  $f_y = 276$  MPa. Further details on the case-study structure and

reinforcement configurations within beams, columns, and beam-column joints can be found in Bracci *et al.* [20] and Aycardi *et al.* [21].

Figure 1: Case-study bare-frame layout (adapted from Bracci *et al.* [20]), placement and arrangement of BRBs.

The design of the BRBs is based on the methodology described in Freddi *et al.* [8]. The BRB design procedure is based on the displacement distribution of the first vibration mode and uses non-linear static analysis of the bare frame and a Single-Degree-of-Freedom (SDoF) simplification for the definition of some design parameters which are related to the retrofit objectives, such as the design displacement ( $d_u$ ); the target ductility of the dissipative braces ( $\mu_d$ ) and the base shear capacity of the dissipative system ( $V_{d,1}$ ).

As shown in Figure 1, the retrofitting is performed by introducing the BRBs in the central bay at each story of the case-study frame. The base shear and the design displacement of the bare frame, defined based on the pushover analysis, are respectively  $V_{f,1} = 180.72$  kN and  $d_u = 0.308$  m where  $d_u$  is selected as the maximum lateral displacement capacity of the bare frame corresponding to the Complete Damage State.

In the present study, the retrofitted configuration investigated is the one where the base shear of the dissipative system ( $V_{d,1}$ ) is selected equal to the base shear of the bare frame ( $V_{f,1}$ ), or in other words, the strength proportion coefficient  $\alpha = V_{d,1}/V_{f,1}$  is assumed equal to 1 [10], hence doubling the base shear resistance of the retrofitted frame. The ductility of the dissipative braces, *i.e.*, dissipative device plus elastic brace ( $\mu_d$ ) is assumed equal to 15. The design method provides properties such as strength  $F_{d,i}$  and stiffness  $K_{d,i}$  of the dissipative braces at each story. Assuming the ductility of the BRB devices ( $\mu_{BRB} = 20$ ), the yielding resistance of the materials for BRB devices ( $f_{y,BRB} = 250$  MPa) and elastic braces ( $f_{y,eb} = 355$  MPa), and based on strength  $F_{d,i}$ , and stiffness  $K_{d,i}$  of the dissipative braces, the properties of the components can be easily derived.

## 2.2 Modelling Strategy

The FE package OpenSees [23] is used to develop a state-of-the-art two-dimensional model of the case-study frame. The non-linear flexural hysteretic response of beams and columns is simulated using the 'beamWithHinges' element that consists of a central elastic element and two plastic hinge regions at the elements ends defined by fiber sections [24]. The effective flexural stiffness of the elastic portion of the element is evaluated by the ratio of the moment and the curvature corresponding to the yielding of the first rebar of the section. The plastic hinge lengths for both beams and columns are evaluated based on Panagiotakos and Fardis [25].

In these regions, fiber sections are defined that consider the spread of plasticity within unconfined (cover) concrete, confined (core) concrete, and layers of longitudinal reinforcement. While the core and cover concrete within the fiber sections are modelled using the non-linear degrading ‘Concrete02’ material model, the ‘Hysteretic’ material model is used to model the longitudinal reinforcements. For this material, the parameters controlling pinching, damage, and degraded unloading stiffness are calibrated such that close agreements are attained between the numerical and experimental results for model validation. The slab is modelled using unconfined concrete material model with an effective width equal to four times the beam's width, as recommended in the ACI 318-89 [22]. The rigid-floor diaphragm is modelled by assigning high axial stiffness to the beams. Gravity loads are distributed on the beams while masses are concentrated at the beam-column intersections.

‘ZeroLength’ shear and axial springs are introduced at the top of each column, by assigning them the ‘LimitState’ uniaxial material accounting for possible brittle failure mechanisms typical of low-ductility RC MRFs. Moreover, a two-node ‘zeroLength’ rotational joint spring and four rigid offsets are used to model the joint behaviour, including the influence of short embedment lengths of bottom reinforcements of beams within the beam-column joints as done in Jeon *et al.* [26]. In this model, beams and columns are continuous, while the joint model controls their relative rotation. The ‘Pinching4’ material model is used to define the beam-column joint response.

The dissipative braces are modelled by two elements in series representing respectively the BRB device and the elastic brace. The ‘steelBRB’ material model [11] is used to describes the hysteretic behaviour of the BRBs while capturing the kinematic and isotropic hardening, along with the tension-compression asymmetry that typically characterizes these devices.

The model both at component- and at global-level has been validated against the experimental results provided by Aycardi *et al.* [21] and Bracci *et al.* [20]. For the BRB devices a calibration has been conducted based on the results of the experimental qualification tests performed by a manufacturer. For additional details on the modelling and validation please refer to Freddi *et al.* [8][16][27].

### 2.3 Uncertain Parameters

The present paper investigates the influence of the uncertainty stemming from device-to-device variation by the definition of story- and system-level fragility curves. As previously discussed, for ‘Displacement-dependent devices’, such as BRBs, the EN 15129 [17] requires quality-control tests to show that the effective (secant) stiffness  $K_{eff,b}$ , and effective damping  $\xi_{eff,b}$  are in good agreement with the prescribed nominal design values and within prescribed tolerance limits. Alternatively, the ASCE/SEI 7-16 [18] controls the variation in terms of device’s force  $F_b$  and area of the hysteretic loop  $E_{loop,b}$  measured during the tests. In both approaches, the two control parameters exhaustively identify the main characteristics of the device behaviour. Therefore, the code-based tolerance limits are implicitly applied to other related parameters.

In the present study, stiffness, force and dissipation capacity variations are numerically reflected within the model by accounting for variations in the area of the BRB devices ( $A_{BRB}$ ) while keeping the material yield strength ( $f_{y,BRB}$ ) as constant. Variation in the BRB device area ( $A_{BRB}$ ) has been chosen as opposed to the material yield strength ( $f_{y,BRB}$ ) as it induces the highest variation in the device response since alteration of the BRB area affects both stiffness, strength and the hysteretic energy dissipated. Device-to-device variation is assumed within the limits set by the codes (*i.e.*,  $\pm 15\%$  in accordance with the EN 15129 [17] and ASCE/SEI 7-16 [18]) and applied independently among the devices at the different stories. The study considers different

values of the tolerance limits assumed and investigates their influence in terms of fragility estimates.

### 3 SURROGATE MODELLING AND PARAMETERIZED FRAGILITY DEVELOPMENT

This section of the paper focuses on the development of parameterized seismic fragility functions for the retrofitted frame that are conditioned on the ground motion intensity measure ( $IM$ ), and the BRB areas across the different stories. The following subsections outline the fragility development procedure that comprises of first constructing an experimental design matrix with uncertain model parameters, metamodel fitting to the response parameter, and eventual parameterized model development using logistic regression.

#### 3.1 Modelling design of experiments

This study adopts a Latin Hypercube Design of experiments that initiates with discretizing the domain of each of the input variables  $A_{BRB1}$ ,  $A_{BRB2}$ , and  $A_{BRB3}$  to  $k$  intervals, where  $k$  is the number of Latin Hypercube samples to be selected for each variable and eventually resulting in an experimental design matrix of  $n \times k$ . Following the discretization, the set of all possible Cartesian products of these discretized intervals constitutes the partitioning of the  $n$ -dimensional sample space to  $k^n$  cells. Consequently, a set of  $k$  cells are chosen of the possible  $k^n$  cells such that the projection of the center of each cell on the respective axes of each parameter generates  $k$  unique points. Consequently, choosing a random point within each selected cell generates a Latin Hypercube Design.

It is noted that the above procedure to generate sample points may still not guarantee an efficient exploration of the sample space. This study adopts a *maximin based Latin Hypercube Design* which selects design points after maximizing the minimum distance between the sample points ensuring that two points are not located too close together. For instance, if  $l$  is a measure of distance (based on the  $L1$  or  $L2$  norm), and  $\mathbb{S}$  is a  $k$ -point design, the smallest distance between any two points  $A_{BRBi}$  and  $A_{BRBj}$  may be given by:

$$\min_{A_{BRBi}, A_{BRBj} \in \mathbb{S}, i \neq j} l(A_{BRBi}, A_{BRBj}) \quad (1)$$

Consequently, a maximin distance design maximizes the minimum distance given in Equation (1) to generate another  $k$ -point design  $\mathbb{S}_M$  such that the minimum distance between the points  $A_{BRBi}$  and  $A_{BRBj}$  now becomes:

$$\min_{A_{BRBi}, A_{BRBj} \in \mathbb{S}_M, i \neq j} l(A_{BRBi}, A_{BRBj}) = \max_{\mathbb{S} \subset \Theta} \left[ \min_{A_{BRBi}, A_{BRBj} \in \mathbb{S}, i \neq j} l(A_{BRBi}, A_{BRBj}) \right] \quad (2)$$

where,  $\Theta$  constitutes the  $n$ -dimensional design sample space. In addition to the maximin based Latin Hypercube design, this study also considers experimental design based on quasi-random sampling. A typical experimental design  $D$  of size  $k \times n$  generate by the Latin Hypercube Design can be represented as shown in Equation (3):

$$D = \begin{bmatrix} A_{BRB1,1} & A_{BRB2,1} & A_{BRB3,1} \\ A_{BRB1,2} & A_{BRB2,2} & A_{BRB3,2} \\ \vdots & \vdots & \vdots \\ A_{BRB1,k} & A_{BRB2,k} & A_{BRB3,k} \end{bmatrix} \quad (3)$$

where each row of the design matrix provides a unique combination of BRB areas within the tolerance limits. In addition to these parameters, a critical parameter of interest is the ground motion intensity  $IM$ . Due to the inherent randomness in ground motion time-histories,  $IM$  is treated as an uncontrollable parameter in the experimental design. The uncertainty associated with ground motions is propagated in this study by pairing each row of the design matrix with a random time-history record and conducting nonlinear dynamic analysis of  $k$ -statistically similar but characteristically different retrofitted building samples. The peak interstory drift ratios for the overall frame are used next to fit multivariate probabilistic seismic demand models and fragility functions as described in the next step.

In the present study, the uncertainty affecting the seismic input in terms of variability in duration, frequency content, and other characteristics of the input expected to act on the system, is taken into account by considering the set of 240 natural records selected by Baker *et al.* [28].

### 3.2 Metamodel fitting to storey level response

Among the various metamodeling strategies, this study adopts the polynomial response surface models to approximate the maximum story and system level response as a function of the ground motion intensity measure and BRB areas. Polynomial response surface models were first developed by Box and Wilson [29] and have been widely adopted for predicting the response of complex engineering systems, such as buildings and bridges. The most widely used response surface models consist of low order polynomial functions. Simpson *et al.* [30] recommended that first order polynomials shall suffice for responses characterized by low curvatures: an assumption that is valid for the present case at hand. Consequently, first order response surface polynomials of the form shown in Equation (4) are adopted because of enhanced goodness-of-fit measures in comparison to first order polynomial models.

$$\hat{y} = \beta_0 + \beta_{IM} + \sum_{i=1}^3 \beta_i A_{BRBi} \quad (4)$$

In this equation,  $\hat{y}$  represents the predicted value of the maximum interstory drift ratio (story level:  $IDR_{max,i}$  or system level:  $IDR_{max}$ ), and  $\beta_0$ ,  $\beta_{IM}$ , and  $\beta_i$  are the regression coefficients obtained using least square principles after fitting the response surface to the response data from nonlinear time history analyses of the retrofitted frame. Table 1 shows the regression coefficients for the polynomial response surface model for each of the three stories as well as the overall frame along with the  $R^2$  goodness of fit measure indicative of the satisfactory response prediction at the story as well as system level.

	Story 1	Story 2	Story 3	Whole Frame
$\beta_0$	0.802	0.800	0.343	0.951
$\beta_{IM}$	1.023	0.978	0.877	1.005
$\beta_1$	-0.079	0.021	0.040	-0.001
$\beta_2$	-0.039	-0.099	-0.013	-0.091
$\beta_3$	0.075	-0.001	-0.192	0.012
$R^2$	0.831	0.891	0.895	0.860

Table 1: Regression coefficients and  $R^2$  estimates corresponding to the polynomial response surface model for the three stories and the overall frame.

The polynomial response surface model utilized in this study also aids in the identification of the critical variables other than  $IM$  that most affect the interstory drift ratios. These are shown in Figure 2(a) through (b) using Pareto charts corresponding to maximum interstory drift ratios

for the individual stories as well as for the overall frame. The left vertical axis of the Pareto charts represents the absolute  $t$ -statistic ratios for the parameters arranged in decreasing order of importance. This statistic is computed as the ratio between the parameter estimate and the corresponding standard error. The right vertical axis represents the cumulative sum of the absolute values of the  $t$ -ratio (in percentage) and elucidates the aggregated explanatory power of variables when jointly considered in succession. As Figure 2 reveals, while  $IM$  emerges as the most critical variable across all stories, the story-level BRB areas affect the response of specific individual stories. In other words, among the three different BRB areas,  $A_{BRBi}$  most affects the response of the  $i^{\text{th}}$  story. This finding is intuitive and also aligns with the seismic design strategy used for the BRBs. For the overall frame, the maximum interstory drift ratio ( $IDR_{\max}$ ) is most dependent on  $A_{BRB2}$  at the second story as shown in Figure 2(d).

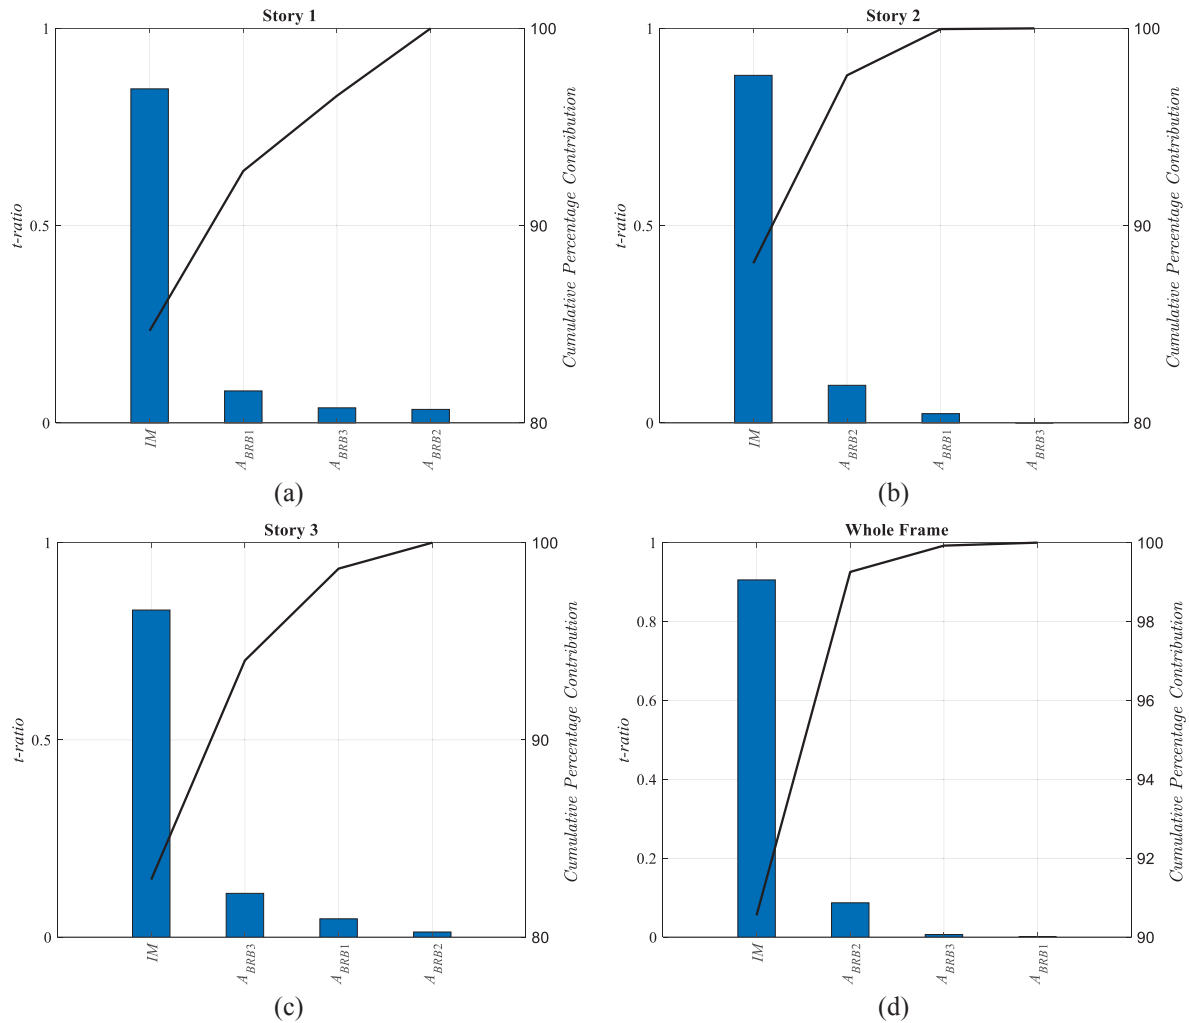

Figure 2: Pareto Charts depicting the contribution of the ground motion intensity measure and BRB areas on the maximum interstory drift ratios for a) Story 1, b) Story 2, c) Story 3, and d) Overall frame.

### 3.3 Parameterized fragility function development

The multidimensional story and system level seismic demand models developed in the previous section are utilized in this stage to develop parameterized seismic fragility functions after comparing with the capacity estimates. The capacity distributions for the individual stories as well as the overall frame are obtained using nonlinear static pushover analysis and are directly adopted from Freddi *et al.* [16]. Comparison between large number of seismic demand and

capacity samples help generate binary survive-failure vectors. These binary vectors are then used to develop time-evolving seismic fragility functions by using the logistic regression approach. Note that other techniques such as naïve Bayes classifier, Probit model, Support vector machines, among others may be also utilized for fragility development. A brief description of the steps involved to develop fragility functions using logistic regression is provided herein [31][32]:

**Step 1:** For a particular building story or the overall frame, sample a large number ( $N_{MC}$ ) of demand estimates from the probabilistic seismic demand models of the maximum interstory drift ratios as elaborated in the previous step. These samples should ideally reflect substantially distinct combinations of the ground motion  $IM$  and the BRB areas ( $A_{BRB1}$ ,  $A_{BRB2}$ , and  $A_{BRB3}$ ).

**Step 2:** Generate  $N_{MC}$  capacity estimates from the capacity distribution of individual stories or the overall frame for the four considered damage states (*i.e.*, Slight, Moderate, Extensive and Complete).

**Step 3:** Compare the demand estimates against the capacity samples and generate a binary vector  $\{\mathbf{bin}\}$  consisting of 1's and 0's, where, 1's represent a story or system-level failure (demand greater than capacity) and 0's represent a story or system-level survival (demand less than capacity).

**Step 4:** Conduct logistic regression using the binary survival–failure vector to determine the story or system-level failure probability for particular damage state  $ds$  as:

$$Pf_{ds|IM, A_{BRB1}, A_{BRB2}, A_{BRB3}} = \frac{e^{\theta_0 + \theta_{IM} \ln(IM) + \sum_{i=1}^3 \theta_{BRBi} A_{BRBi}}}{1 + e^{\theta_0 + \theta_{IM} \ln(IM) + \sum_{i=1}^3 \theta_{BRBi} A_{BRBi}}} \quad (5)$$

where,  $\theta_0$ ,  $\theta_{IM}$ , and  $\theta_{BRBi}$  ( $i = 1$  to 3) are the story or system-level logistic regression coefficients for damage state  $ds$ . Table 2 below enlists the logistic regression coefficients that are utilized in the next section of the paper to derive seismic fragility curves for nominal BRB areas as well as quantify the effect of uncertainty on fragility estimates.

	Story 1	Story 2	Story 3	Whole Frame
$\theta_0$	8.140	2.071	0.405	-3.013
$\theta_{IM}$	6.102	6.014	6.739	11.942
$\theta_{BRBi}$	-0.023	-0.062	-0.010	0.038
$\theta_{BRBi}$	-0.582	-0.526	-0.595	-0.538
$\theta_{BRBi}$	0.072	0.187	0.133	0.052

Table 2: Logistic regression coefficients at story and system level for seismic fragility development.

## 4 RESULTS AND DISCUSSIONS

Unlike unidimensional seismic fragility functions as typically adopted for seismic vulnerability assessment of retrofitted frames, the parameterized fragility models developed in the earlier section offers several advantages. Firstly, for the nominal BRB areas, these fragility functions provide prompt estimates of individual story and system-level fragilities. For instance, Figure 3(a) depicts the individual story fragilities, as well for the whole frame corresponding to the design BRB areas. As expected, the fragility curve for the overall frame emerges

predominantly more fragile than the individual stories. Additionally, among the different stories, the second story emerge as the most fragile and lies in close proximity to the system-level vulnerability curve. Secondly, without the need of additional computationally expensive finite element model runs, the parameterized fragility functions help investigate the influence of BRBs' property variation on retrofitted frame fragility. While Section 3 earlier showed that  $A_{BRB2}$  emerge as a critical parameter affecting the system-level frame response ( $IDR_{max}$ ), Figure 3(b) depicts the variation of retrofitted frame fragility as a function of  $A_{BRB2}$  variation within  $\pm 20\%$  of design estimates for moderate damage state, while holding other BRB areas ( $A_{BRB1}$  and  $A_{BRB3}$ ) constant at nominal values. As expected, the figure shows that higher  $A_{BRB2}$  areas tend to reduce the retrofitted frame fragility, however high BRB areas may not be optimal from the design perspective.

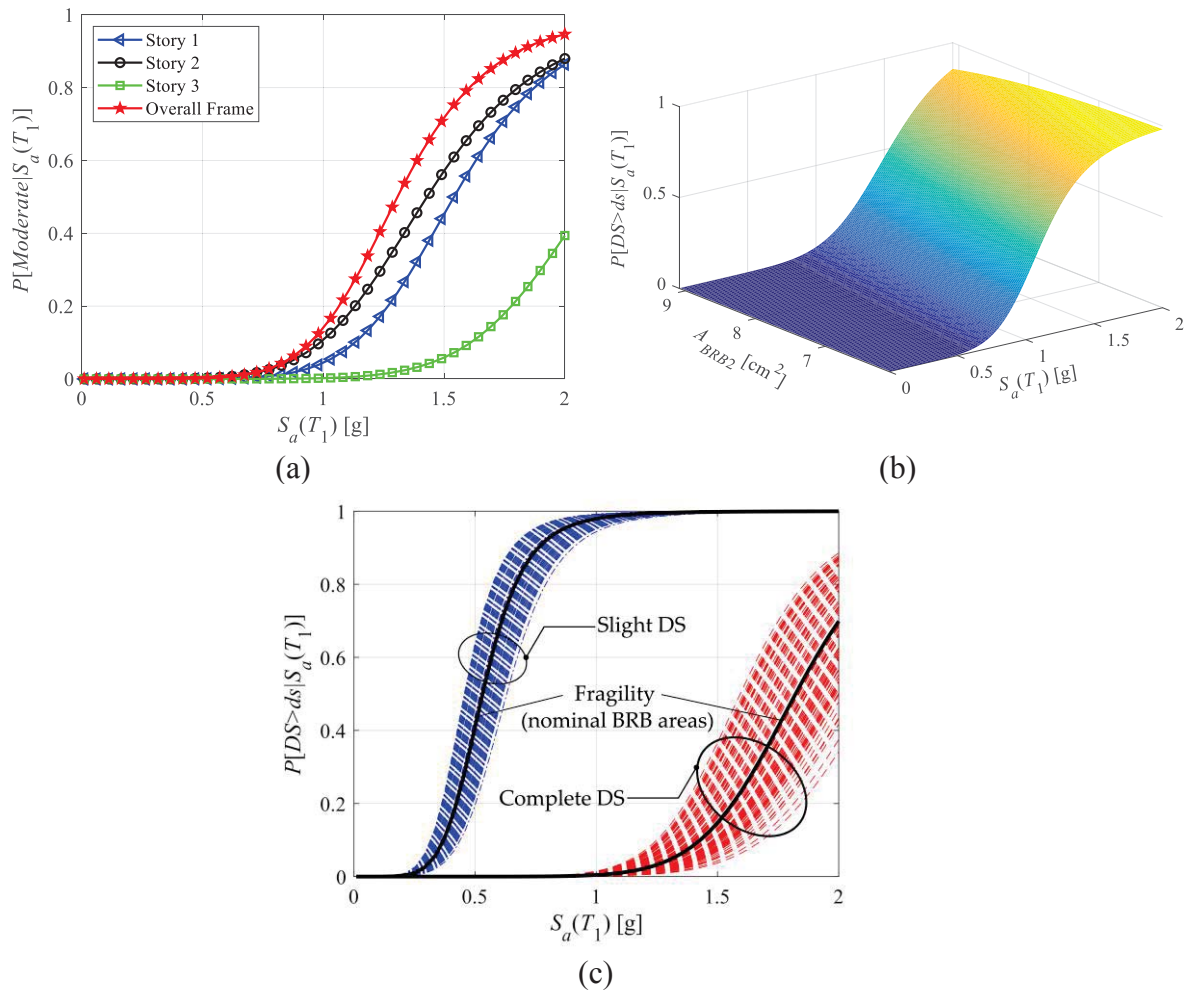

Figure 3: a) Seismic fragility curves for different stories as well as the retrofitted frame corresponding to the moderate damage state for nominal BRB areas, b) variation of retrofitted frame vulnerability with  $\pm 20\%$  variation of  $A_{BRB2}$ , and c) fragility bands depicting the uncertainty in retrofitted frame fragility for the slight and complete damage states due to variations in  $A_{BRB1}$ ,  $A_{BRB2}$ , and  $A_{BRB3}$  within  $\pm 20\%$  of design limits.

The parameterized seismic fragility functions also help estimate the bounds of fragility estimates corresponding to independent variation of the BRB areas across the three stories. Figure 3(c) shows the departures from the “mean” fragility estimates of the retrofitted frame for the slight and complete damage states due to variations in  $A_{BRB1}$ ,  $A_{BRB2}$ , and  $A_{BRB3}$  within  $\pm 20\%$  of design estimates. These fragility bounds also underline the wide variability in retrofitted frame fragilities as a consequence of potential randomness in the BRB areas within the prescribed

code limits. The upper and lower values of the median estimates are observed to range from 0.45 g to 0.62 g for the slight, 1.10 g to 1.51 g for moderate, 1.41 g to 1.91 g for extensive, and 1.53 g to 2.10 g for the complete damage states respectively.

## 5 CONCLUSIONS

Seismic fragility assessment of retrofitted structures typically uses conventional techniques for vulnerability evaluation that may often emerge as tedious in terms of computer run-time. Moreover, to ascertain the influence of parameter variation on building fragility one may need to resort to costly re-analysis under dynamic loads. This study focuses on a computationally efficient technique to assess the impact of variation in BRB device parameters on story level as well as overall retrofitted frame fragility.

To achieve the above objective, first an experimental design matrix is constructed that provides an optimum combination of BRB device areas (chosen as the parameter of interest) within  $\pm 20\%$  of nominal estimates while offering an efficient exploration of the sample space. Next through the results obtained from the nonlinear dynamic analysis of statistically different yet nominally identical frame models polynomial response relationships are developed between the story and system level maximum interstory drift ratios. Comparison of t-statistic ratios indicate that other than the ground motion intensity measure, individual story level BRB device areas emerge most critical for response prediction for that specific story. For the overall frame, the device area at the second story has the most controlling effect. Next, the developed polynomial demand models are compared with capacity estimates to derive parameterized fragility functions using logistic regression techniques. These functions offer significant advantages over traditional intensity-measure-only dependent fragility curves and helps prompt assessment of a) individual and overall frame fragility for nominal BRB area estimates, b) influence of parameter variation on story and system level fragility, and c) development of uncertainty bands to estimate the departures from “average” fragility estimates when variations in device areas are taken into consideration. For the retrofitted case-study frame, the upper and lower values of the median estimates are observed to range from 0.45 g to 0.62 g for the slight, 1.10 g to 1.51 g for moderate, 1.41 g to 1.91 g for extensive, and 1.53 g to 2.10 g for the complete damage states respectively.

Future work on this topic will investigate the influence of BRB device variability on different case study structures and will consider different retrofit levels (*i.e.*, different proportions of the base shear between the MRF and the BRBs). In these cases, due to the variation of the structural vibration period, an alternative intensity measure needs to be evaluated, this representing one of the main challenges for the extension of the proposed methodology.

### Abstract

*This study illustrates the development of a modeling strategy for simulating the seismic response of structures mounted on elastomeric bearings with a low shape factor (LSF). These bearings can be employed to achieve a three-dimensional seismic isolation of structures, due to their low vertical and horizontal stiffness. The first part of this work investigates the mechanical behaviour of LSF bearings by means of three-dimensional Finite Element (FE) analysis in Abaqus. The FE results provide a numerical evaluation of the horizontal, vertical, and rotational stiffness of the bearings. These are used in the second part of the study to develop in SAP2000 a simplified model of a structure with LSF bearings tested experimentally on the shaking table at University of Naples Federico II. The study results show that the developed model can be effectively used to simulate the response of the isolated structure under different earthquake inputs.*

**Keywords:** Isolation system, low shape factor bearing, FE simulation, hyperelastic material.

---

## 1 INTRODUCTION

Elastomeric bearings are among the most common types of isolation system for protecting structures from earthquakes. They consist of multiple layers of rubber vulcanized to steel reinforcing layers that produce a combination of vertical stiffness and horizontal flexibility [1]. The geometry of these bearing is characterized by the primary shape factor,  $S$ , which defines the ratio of the loaded area to the area free to bulge for an individual rubber layer [2]–[4]. Shape factor values of 10–20 are typically used to guarantee high critical load capacities while keeping a low horizontal stiffness. On the other hand, bearings with high  $S$  values are significantly heavy due to the large number of steel plates and consequently expensive in terms of production and installation. Moreover, superstructures isolated with high vertical stiffness bearings are characterized by low vibration periods in the vertical direction, causing problems for critical facilities such as nuclear power plants or hospitals hosting sensitive equipment needing protection against the effects of vertical component of earthquake inputs.

The concept of low shape factor (LSF) rubber bearings as a way to achieve an economic 3D isolation has been investigated by other researchers [5] [6]. Recently, it has also been the object of an extensive experimental campaign carried out by Cilento et al. [7] to demonstrate the effectiveness of isolating a structure with a very LSF.

The aim of this paper is to present a finite element (FE) modelling strategy for simulating the seismic response of structures equipped with LSF bearings. The proposed strategy is validated considering the results of the experimental campaign carried out by Tun Abdul Razak Research Center (TARRC) and University of Naples Federico II on a structural prototype with LSF rubber bearings made with lightly filled natural rubber [8]. The first part of the paper focuses on the simulation of the bearing behaviour in Abaqus [9], using a three-dimensional modelling approach for the LSF bearings, with a hyperelastic constitutive law for the rubber calibrated using the double shear test results. In the second part of the paper, a simplified model based on a linearized description of the bearing mechanical behaviour is developed in SAP2000 [10]. This model is validated by simulating the shaking table tests performed on a structure isolated with LSF bearings. The numerical results of the analyses shed light on the possibility of using simplified device models for the preliminary seismic assessment of isolated structures mounted on LSF bearings.

## 2 NUMERICAL SIMULATIONS OF MATERIAL AND BEARING TESTS

This section describes the three-dimensional (3D) numerical models developed in Abaqus [9] to simulate the tests on the double shear testpieces and the elastomeric bearings carried out at TARRC [7]. The double shear cylindrical testpieces consisted of two rubber layers bonded to metal parts, as shown in Figure 1a, and were subjected to sinusoidal shear displacement histories. Figure 1b illustrates the laminated bearing considered in the test, which consists of three layers of rubber 19mm thick and sides 100x100 mm, designed to achieve a shape factor  $S = 1.32$ . The bearing was subjected simultaneously to static compression and dynamic shear loading in a double shear configuration. The testing sequence consisted of two cycles of sinusoidal displacement at increasing shear strain amplitudes [8] [11].

Figure 1: (a) Double shear test piece geometry, (b) Elastomeric bearing geometry

In the numerical models, the rubber is described using a hyperelastic constitutive material. Hyperelastic materials are defined by the strain energy potential  $W$ , the strain energy stored in the material per unit of reference volume, as a function of the strain at that point in the material. Yeoh constitutive relationship is used in this study and the strain energy potential is derived from the reduced polynomial strain energy potential that is a function of only the deviatoric strain invariant  $I_1$  and has the following expression:

$$W = \sum_{i=1}^N C_{i0} (I_1 - 3)^i \quad (1)$$

where  $C_{i0}$  are material parameters. The Yeoh form is obtained for a number of terms  $N$  equal to 3. The values of material parameters  $C_{i0}$  in the equation (1) can be obtained from the double shear experiments and are shown in Table 1.

Model parameters	C10 [MPa]	C20 [MPa]	C30 [MPa]
Yeoh	0.3	-0.005	0.000311

Table 1 Material parameters for Yeoh hyperelastic material model

Rayleigh damping is used in the numerical analysis to describe the damping property of the rubber material. The coefficients for the Rayleigh damping are calculated using a damping ratio of 1% for the first and second modes of the isolated system described in section 3. The coefficient  $\alpha$  for the mass matrix and the coefficient  $\beta$  for the elastic initial stiffness matrix are calculated to be 0.067926 and 0.00080, respectively.

The shear stiffness values obtained numerically for different maximum shear strain have been compared with the experimental data, as shown in Figure 2a. A good agreement between simulations and the test is found for all the investigated shear deformation amplitudes, apart from low values of shear strains.

The estimates of the equivalent damping ratio of the rubber block from FE analysis results for different levels of strain amplitude are shown in Figure 2b, where they are compared with the corresponding values obtained experimentally. Although a simple description of the damping is used, a good agreement is found between numerical and experimental results. It is noteworthy that more advanced description of the damping, e.g. using a Prony series approach [13] or the Bergstrom Boyce model [14], would require further tests in order to calibrate the higher number of model parameters.

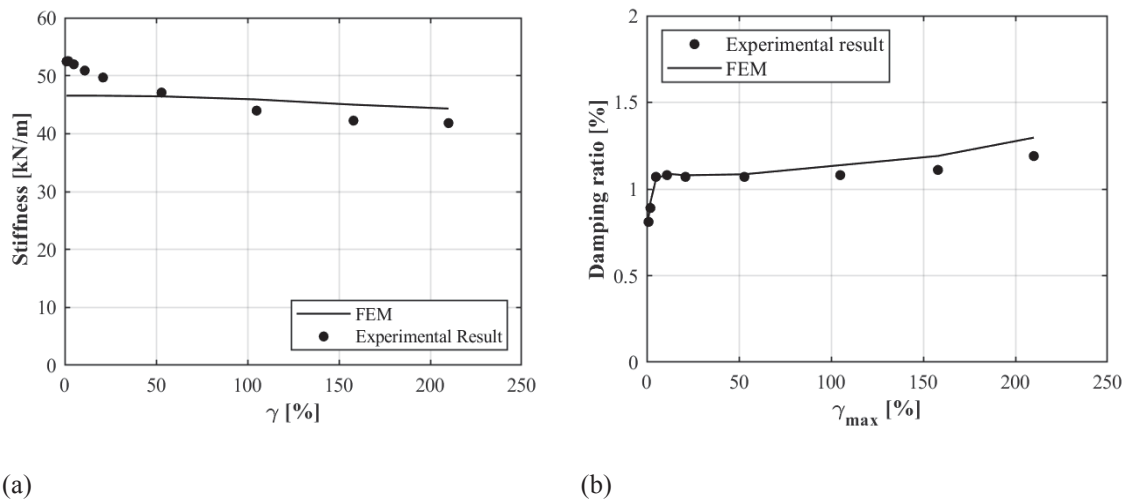

Figure 2: Experimental and numerical values of (a) Shear stiffness for different maximum shear strains (b) Equivalent damping ratio for different maximum shear strains

The LSF bearing FEM model is illustrated in Figure 3. The rubber layers, the intermediate steel shim plates and end plates are modelled using C3D8H elements that are available in the Abaqus library [9]. The tie contact between steel and rubber layers of the bearing is expressed by contact pair option available in Abaqus. The displacement boundary conditions are applied to the top end plate while performing compression and shearing tests, whereas the bottom anchor plate is fixed in all degrees of freedom.

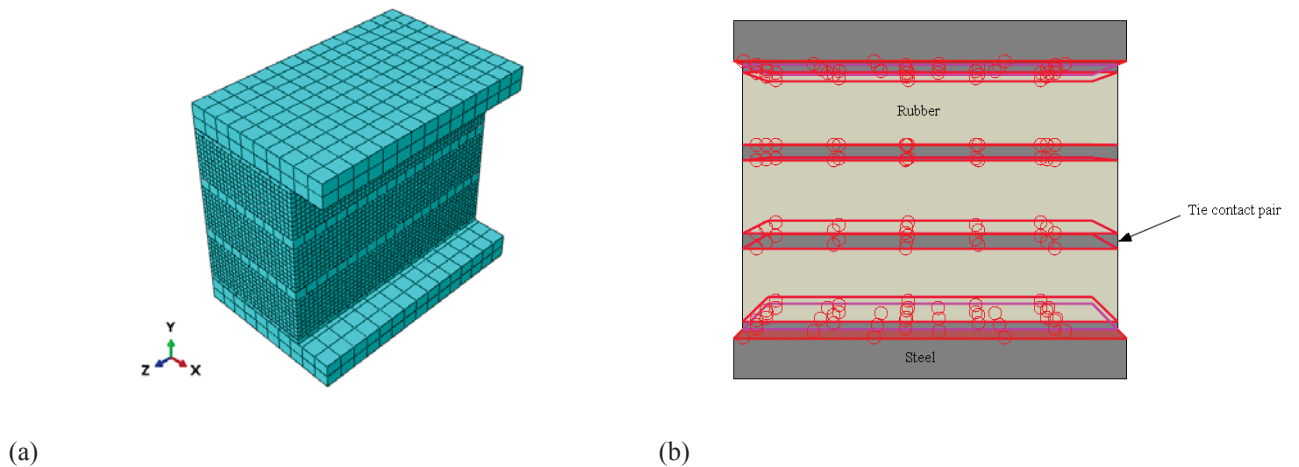

Figure 3: Elastomeric Bearing: (a) Meshing, (b) Details of connections between various layers.

A vertical downward displacement was first imposed at the top plate, until a compressive load of 19kN is achieved, being the gravity load in the shaking table tests, described in the next section. Subsequently, two cycles of sinusoidal displacements are applied while preventing vertical motion and rotation of the top plate.

Figure 4a shows the changes with the maximum amplitude of average shear deformation of the horizontal secant stiffness of the bearing. These have been evaluated both numerically and experimentally as the ratio of base shear force to the maximum displacement at each incremental step. In general, the experimental and numerical values are very close, except for low shear strains, for which the numerical model is more flexible. The bearing equivalent viscous damping has been evaluated numerically and compared with the experimental results, as

shown in Figure 4b. Both experiment and numerical results show that with the increase of shear strains, the damping decreases.

Figure 4c compares the estimates of the initial shear stiffness at zero shear displacement for increasing values of the applied vertical displacement according to the numerical FE model and the experimental results.

Figure 4: (a) Secant shear stiffness-average shear strain relation (b) Equivalent damping ratio at different levels of shear strain (c) Stiffness vs vertical displacement. Experimental values taken from [11].

The numerical model provides an overall good estimate of the shear stiffness for increasing of compression levels. In general, the horizontal stiffness reduces with the increase of the vertical load, and the condition of instability is attained when it becomes zero. It is noteworthy that the observed buckling load is 50% higher than the applied compression load of 19kN and it is also 3 times higher than the critical load evaluated according to the theory of Gent and of Koh and Kelly [15] [16]. It is also interesting to observe that the ratio between the initial horizontal and vertical stiffness is about 43, which is significantly lower than the values typical of high shape factor bearings ([1], e.g. about 800 for  $S=12$  in Tubaldi et al. [17], which deals with isolation bearings for bridges).

### 3 SHAKING TABLE TESTS

#### 3.1 Prototype and test description

This subsection describes the shaking table tests carried out at the Department of Structures for Engineering and Architecture of University of Naples Federico II on a prototype base-isolated building with LSF bearings [8]. The steel superstructure is composed of one level and has a total height of 2900mm. The plan dimensions of the structure are 2500x2000mm with concrete slab placed on the roof of the structure, having a depth of 25mm, and concrete blocks added to the base level to achieve a total mass  $M_{tot} = 7.7$  tons. The columns have a box section 150x150x15mm. The beams of the top floor are pinned to the columns and are hot-formed square hollow sections 120x120x12.5mm. The four perimetric beams at the base of the frame have HEM 160 profile. The bearings are identical to those tested at TARRC. The same mock-up has been recently used for bi-directional tests on recycled rubber and fibre-reinforced unbounded isolators [18][19]. Ground motions were applied along the direction in which the frame span is 2500 mm. The vibration period of the fixed-base structure is  $T_s = 0.24$  s. The isolation system of the scaled prototype was designed to achieve a horizontal vibration period  $T_{is} = 0.92$  s, estimated from an assumed value of the rubber shear modulus of 0.5MPa and considering the superstructure as rigid and the bearings as infinitely stiff in the vertical direction. Under these simplifying assumptions, the isolation period can be expressed as  $T_{is} = 2\pi\sqrt{(M_{tot}/K_{is})}$ , where  $K_{is}$  is the total stiffness of the bearings in the horizontal direction. It is noteworthy that the system was designed considering a geometry scale factor of

1/3 and an elastic modulus scale factor of 1. Therefore, according to the dynamic similitude rule, the equivalent period of the full-scale structure is  $T_{fs} = 1.59$  s, (i.e.  $T_{fs} = \sqrt{3}T_{is}$ ). A set of seven waveforms was selected from the European strong-motion database, whose main characteristics are described in Table 2.

### 3.2 Simulation of shaking table tests

Figure 5 shows the simplified FEM model of the isolated structure developed in SAP2000 [10]. The steel columns and beams of the frame are assumed to remain elastic and are modelled with beam elements assigning a Young's modulus of 210000MPa, a Poisson's ratio of 0.3, and mass density of 7.8E-09 ton/mm<sup>3</sup>. The mass at top and bottom level is 2.05 and 1.8 tons respectively, so that the vertical load applied to the bearing is 19kN. The isolators are modelled using the two-node link linear elements [10] connecting the bottom of the base beam to the ground (Figure 5).

Figure 5: Front view of the base isolated structure configuration and detail of the isolation system

Table 3 shows the values of the stiffness assigned to the two-node link elements, where  $K_v$ ,  $K_h$  and  $K_r$  are the vertical, shear and rotational stiffnesses, respectively. These values are de-

terminated by considering the bearing model developed in Abaqus and applying a small axial displacement, shear displacement and rotation on the bearings compressed by a vertical load of 19 kN.

N/mm	N/mm	Nmm
2209	51	1180000

Table 3: Link Element Properties

A Rayleigh damping model has been assumed and the damping ratio of the first two modes of the base isolated structure has been set equal to  $\zeta = 0.02$ . In contrast to the definition of damping on a 3D numerical model, that is related to the material property, the damping ratio in this case needs to be specified to the whole bearing. The adopted value of  $\zeta$  refers to the equivalent damping ratio of bearing correspondent to 80% of shear strain, shown in Figure 4b. Seismic analyses are performed using the developed model. Displacement history of isolator and top structure horizontal accelerations resulting from numerical model are compared to the recorded ones for Etolia earthquake input, as shown in Figure 6a-b. In general, it can be observed that assuming a linearized behaviour of the bearings superimposed on the finite strains induced by the vertical static loading on the bearing provides a good approximation of the response in the case of Etolia earthquake input.

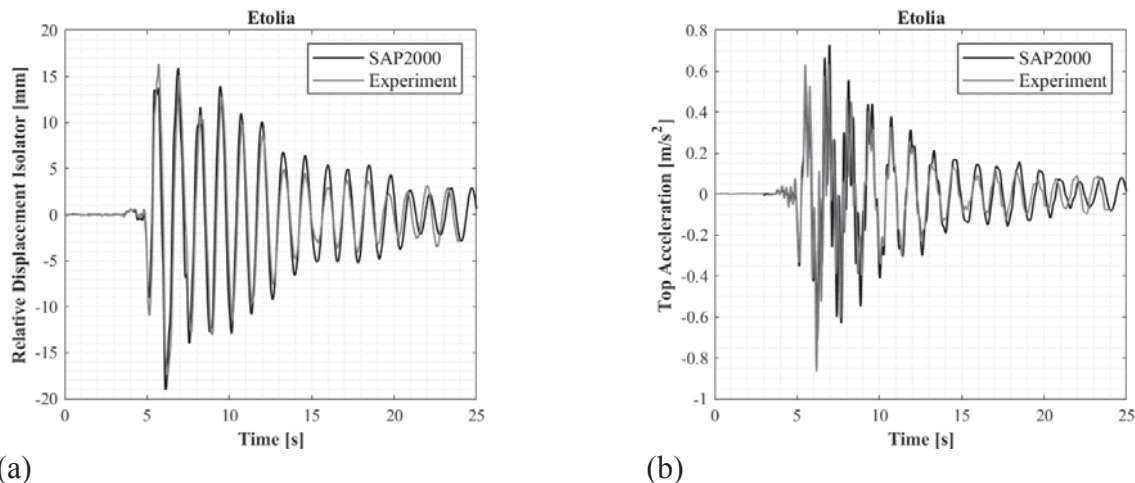

Figure 6: (a) Relative Displacement Isolator time history (b) Acceleration at the top of the superstructure

Table 4 shows the numerical-experimental comparisons in terms of maximum absolute values of the isolator deflection, interstorey drift and acceleration at the top of the structure. The response of the superstructure is slightly underestimated, and this may be due to the assumption of a rigid connection between the columns and the base.

#### 4 CONCLUSION AND FUTURE RESEARCH NEEDS

This study investigates numerically the mechanical behaviour of elastomeric bearings with low shape factor (LSF) under compressive and shear loading, and the dynamic behaviour of structures mounted on them. The first part of the paper illustrates the development of a three-dimensional (3D) numerical model in Abaqus for simulating the experimental tests conducted at Tun Abdul Razak Research Center (TARRC) rubber research center on LSF rubber bearings with low damping. It is shown that the Yeoh hyperelastic material model, calibrated against material double-shear tests, can be used to accurately describe the complex nonlinear shear response of compressed LSF bearings.

In the second part of the paper, the shaking table tests carried out on a model isolated structure on LSF bearings performed at University of Naples Federico II are simulated using a simplified numerical model. The prototype isolated structure is analyzed using SAP2000 under different earthquake loadings and the numerical estimates of the response are compared with the experimental ones. The isolators are described using two-node links with linear elastic behaviour and vertical, shear and rotational stiffnesses are estimated by performing numerical analyses of the LSF bearing in Abaqus. In general, it is observed that the development of simple FEM model for the tested prototype isolated structure can be used for preliminary assessment and design purposes due to the good agreement between numerical responses and experimental results.

Further studies will include the development of advanced numerical models to evaluate the behaviour of LSF bearings and their capability of providing full three-dimensional isolation. Moreover, the response of LSF bearing made with high damping rubber compounds, characterized by more complex behaviour, will be investigated.

### Abstract

The goal of this study is to determine experimentally the inelastic response modes of seismically isolated structures. A steel specimen is designed and constructed to simulate the dynamic behavior of a Single-Degree-Of-Freedom (SDOF) system. The specimen is seismically isolated with four friction pendulum bearings and excited by a group of earthquake ground motion records using the shaking table of ETH Zurich Laboratory. A mechanical clevis connection consisting of two hinges and two replaceable steel coupons is designed and constructed to facilitate the parametric investigation of the inelastic response of the isolated structure for varying values of its strength. Two fundamentally different inelastic response modes have been observed during the excitation of the structure: A response mode dominated by large sliding displacement demand in the isolators and a response mode characterized by large displacement ductility demand in the isolated structure. This paper shows the effect of the design parameters of the isolation system and the isolated structure on the manifestation of these two response modes, thus paving the way for the understanding of the inelastic response of seismically isolated structures subjected to extreme earthquake ground motions.

## 1 INTRODUCTION

The attractive characteristics of seismic isolation on the seismic protection of structures through the use of frictional or elastomeric devices have been demonstrated by many researchers in the past [1-3]. The current seismic code provisions prescribe the elastic design of these structures for a design-basis earthquake event. In view of these provisions, most of the existing studies investigating the dynamic response of seismically isolated structures use an elastic dynamic model for the simulation of the seismic response of the isolated structure.

However, seismically isolated structures can be subjected to inelastic behavior and damage, when they are excited by earthquake ground motion with intensities exceeding the design seismic hazard level. Furthermore, seismically isolated structures can manifest inelastic behavior even for ground motion intensities corresponding to the design hazard level, when they are unintentionally constructed with lower strength than the value prescribed by the code provisions [4-7]. The investigation of such behavior of existing seismically isolated structures sheds light on their reliability and robustness compared to fixed-based structures, as defined by Castaldo et al. [8, 9], Tsang [10] and Peng et al. [11].

In view of these challenges, the inelastic behavior of seismically isolated structures has been investigated in several studies in the past. Kikuchi et al. [12] and Cardone et al. [13] investigated analytically the inelastic behavior of seismically isolated structures, concluding that the behavior of these structures after they yield is substantially different from the corresponding fixed-based structures. Ragni et al. [14] presented the seismic damage and collapse risk of seismically isolated buildings, designed according to the Italian seismic code provisions. Tsiavos et al. [15] determined analytically and verified experimentally [16, 17] the relations between the strength reduction factor  $R_y$ , the ductility demand  $\mu$  and the fixed-based vibration period  $T_n$  of seismically isolated structures.

Nevertheless, these studies did not focus on the two different failure types that characterize the inelastic behavior of seismically isolated structures: The failure of the isolators and the occurrence of damage in the isolated structure.

Along these lines, the present study aims to illustrate experimentally the design parameters that lead to the two different failure types of seismically isolated structures. A steel structure is seismically isolated with four friction pendulum bearings and subjected to an ensemble of recorded, unidirectional earthquake ground motion excitations. The design and construction of a mechanical clevis connection allows the variation of the strength of the isolated structure.

## 2 EXPERIMENTAL CONFIGURATION

### 2.1 Design of the experimental setup

The experimental setup shown in Fig. 1 entails a 1.9m tall steel structure, which is seismically isolated using four friction pendulum bearings. The seismically isolated structure is excited by an ensemble of earthquake ground motion excitations using the 2m x 1m unidirectional shaking table of the ETH Laboratory.

The steel structure was designed with a fixed-base vibration period  $T_n=0.5s$ , similar to the one of a 2-4 story building. The structure comprises a steel frame with a lumped mass  $m_s=250kg$  rigidly fixed on top. The frame consists of two hollow rectangular columns connected at regular intervals by seven horizontal struts. A mechanical clevis connection consisting of two hinge elements and a couple of replaceable steel coupons was designed to enable a

**Fig. 2.** Top view and cross sections of the mechanical configuration comprising two replaceable steel coupons (Dimensions in mm).

**Fig. 3.** Drawing of the friction pendulum bearings used in the experimental setup, as designed by the company Mageba SA.

**Fig. 4.** Constructed experimental setup at the ETH Structures Laboratory.

## 2.2 Ground motion ensemble

The seismically isolated structure shown in Fig. 1 was excited by 8 different ground motion records obtained from the PEER Strong Ground Motion Database. The characteristics of the applied records are shown in Table 1. The recorded motions, scaled to different Peak Ground Acceleration (PGA) levels, are applied in the X-direction of the experimental setup shown in Fig. 1, using the unidirectional shaking table of the ETH Structures Laboratory with a stroke  $d_{max}=240\text{mm}$ . Each ground motion record was applied twice to the seismically isolated structure, characterized by two different strength values: First, a seismically isolated structure with strength reduction factor  $R_y=1.5$ , engineered through the use of steel coupons with reduced section (Fig. 2) of diameter  $D_{red}=5\text{mm}$ , was subjected to the ground motion record. Second, a seismically isolated structure with strength reduction factor  $R_y=2$ , engineered through the use of steel coupons with reduced section (Fig. 2) of diameter  $D_{red}=4\text{mm}$ , was subjected to the same ground motion record.

## 2.3 Instrumentation

The attachment of 6 uniaxial accelerometers and 6 displacement markers to the experimentally investigated structure shown in Fig. 1 enables the continuous monitoring of the acceleration and the displacement time history response of the structure during the shaking table motion.

### 3 SHAKING TABLE INVESTIGATION

#### 3.1 Response dominated by inelastic behaviour of the seismically isolated structure

The presented structure (Fig. 1) was first excited by the 17.5% scaled-down 1989 Loma Prieta ground motion acceleration record (No. 7 in Table 1), shown in Fig. 5. The experimentally derived displacement time history response of the isolated structure designed with a strength reduction factor  $R_y=1.5$  relative to the isolators is shown in Fig. 6. The experimentally observed displacement time history response of the seismic isolation system relative to the shaking table motion is shown in the same Figure.

**Fig. 5.** 17.5%-scaled Loma Prieta ground motion acceleration record.

**Fig. 6.** Displacement time history response of the seismically isolated structure with a strength reduction factor  $R_y=1.5$  and the seismic isolation system subjected to the 17.5%-scaled Loma Prieta ground motion.

After the initiation of yielding, the isolated structure manifested significant inelastic behavior, leading to a maximum inelastic displacement  $u_{max}=40.2\text{mm}$  and a ductility demand  $\mu=u_{max}/u_y=40.2\text{mm}/20\text{mm}=2.01$ . The maximum sliding displacement of the seismic isolation

system was not significant for this ground motion excitation, reaching a maximum value of 19.8mm for a dimensionless friction ratio  $\Pi_2 = \mu_f g / \text{PGA} = 0.62$ , as defined by Tsiavos et al. [15].

### 3.2 Response dominated by the sliding displacement of the seismic isolation system

The experimentally derived response of the seismic isolation system was substantially different when the seismically isolated structure (Fig. 1) was subjected to the 35% scaled-down San Fernando ground motion acceleration record (No. 1 in Table 2), shown in Fig. 7.

**Fig. 7.** 35%-scaled San Fernando ground motion acceleration record.

**Fig. 8.** Displacement time history response of the seismically isolated structure with a strength reduction factor  $R_y = 1.5$  and the seismic isolation system subjected to the 35%-scaled San Fernando ground motion.

As shown in the displacement time history response of Fig. 8, the isolated structure manifested significant inelastic behavior in this case as well, despite the earlier and more pronounced activation of the seismic isolation system. The emerging ductility demand in this case (for the same strength reduction factor  $R_y=1.5$ ) in the isolated structure was  $\mu=u_{max}/u_y=37.4\text{mm}/20\text{mm}=1.87$ . Furthermore, the maximum sliding displacement of the seismic isolation system relative to the shaking table was in this case 125mm, much higher than the corresponding sliding displacement of 19.8mm observed for the Loma Prieta ground motion. This large sliding displacements usually manifest themselves during excitations of the seismically isolated structure by long-period ground motion records, as observed by Tsiavos et al. [19, 20], Banovic et al. [21], De Domenico et al. [22] and Gandelli et al. [23].

### 3.3 Damage Type

Two different limit states have been identified in this study to quantify the potential occurrence of damage in a seismically isolated structures: The exceedance of a predetermined ductility demand level in the seismically isolated structure indicating damage in the structure; and the exceedance of a predefined isolator displacement, which is related to a potential damage in the isolators.

The exceedance of the ductility demand level  $\mu=2$  was chosen to quantify the manifestation of severe damage in the isolated structure. As the current code provisions for seismically isolated structures prescribe the elastic design of these structures, the detailing of these structures is usually not sufficient to facilitate high ductility capacity in the isolated structure.

The exceedance of an isolator displacement corresponding to 90% of the isolator displacement capacity  $d=150\text{mm}$  was chosen to quantify the occurrence of damage in the seismic isolation system. Furinghetti et al. [5] have experimentally evaluated and determined the extra-stroke displacement capacity of curved surface slider devices, which is limited by the maximum contact pressure that can be tolerated by the installed sliding material. This extra-stroke displacement capacity was not considered in this study, but it can be further investigated by future studies on the same topic.

As shown in Tables 2 and 3, the value of the dimensionless friction ratio  $\Pi_2=\mu g/\text{PGA}$ , as defined by [15], indicated the predominant response and damage mode of the system for the case of a strength reduction factor of the isolated structure  $R_y=1.5$ : Values of  $\Pi_2$  smaller than 20% were correlated with high sliding displacement and potential damage in the seismic isolation system. Nevertheless, values of  $\Pi_2$  greater than 30% led to high ductility demand and damage concentrated in the seismically isolated structure. This variability in the response modes of the system for  $R_y=1.5$  indicates that the response is also influenced by the frequency content of the ground motion characteristics.

However, the design of a weaker isolated structure with  $R_y=2$  led to high ductility demand and concentration of damage in the seismically isolated structure for all the ground motion records used in this study. The sliding displacement of the seismic isolation system was substantially lower in this case, indicating that the response mode of the isolated structure subjected to extreme earthquake events is significantly influenced by the strength of the isolated structure: The reduction of the strength of the isolated structure leads to higher amount of damage in the isolated structure, which is not influenced by the ground motion characteristics.

**Table 2.** Experimentally and analytically derived response for  $R_y=1.5$ .

No.	Strength reduction factor $R_y$	Experimentally observed ductility demand $\mu$	Dimensionless friction ratio $\Pi_2$ (%)	Experimentally observed maximum sliding displacement of the seismic isolation system (mm)	Damage type
1	1.5	1.87	24	125	-
2	1.5	1.96	19	148.3	Seismic isolation system
3	1.5	1.78	13	147.4	Seismic isolation system
4	1.5	2.03	39	56.9	Isolated structure

#### 4 CONCLUSIONS

This study shows experimentally the effect of the design parameters of the seismic isolation system and the seismically isolated structure on the response modes of seismically isolated structures subjected to extreme earthquake events. This effect is demonstrated through a shaking table investigation of the response of a seismically isolated steel structure, subjected to a strong earthquake ground motion excitation ensemble. The tested steel structure was seismically isolated with four friction pendulum bearings. The steel structure was equipped with a mechanical clevis connection comprising two hinges and a pair of replaceable steel coupons. The coupons are designed to yield before the other components of the structure and can be replaced after every shaking table test, thus allowing the experimental seismic fragility analysis of structures.

The shaking table investigation demonstrated the two different fundamental response modes of seismically isolated structures, subjected to above-design earthquake ground motion excitation: A mode characterized by excessive damage of the seismically isolated structure but limited damage in the isolators and a mode dominated by excessive isolator displacement and less damage in the isolated structure.

The two different seismic damage modes of a seismically isolated structure emerging from these two response modes were quantified based on two selected limit states. For the case of a seismically isolated structure designed with a strength reduction factor  $R_y=1.5$ , both damage modes were observed. These modes were strongly correlated with the value of the dimensionless friction ratio  $\Pi_2$ : Values of  $\Pi_2$  smaller than 20% were correlated with damage in the seismic isolation system, while values of  $\Pi_2$  bigger than 30% led to damage concentrated in the seismically isolated structure. However, the weaker seismically isolated structure designed with  $R_y=2$  manifested only damage in the isolated structure and lower sliding displacement of the isolation system, when subjected to the same ground motion excitation ensemble.

### Abstract

*The modeling of large-scale reinforced concrete (RC) structures through 3D detailed modeling is not feasible due to the excessive computational demand that is required during different phases of the analysis. Especially when the overall objective is to perform nonlinear dynamic analysis of RC structures that also take into account the soil-structure interaction effect by discretizing the soil domain with hexahedral elements. These large-scale models have a significant computational demand when analysed, where the use of high-performance computing and parallel solution algorithms is currently the only solution in achieving reasonable computational times. One of the computationally demanding processes during this type of analysis, is the embedded rebar mesh generation, where millions of elements have to be created. This research work proposes a new load distribution algorithm that optimizes the numerical response of a previous parallel embedded rebar mesh generation algorithm incorporated in Reconan FEA. After the implementation of the proposed parallel algorithm, it was found that the computational time was decreased by an average of 57.48% compared to the performance of the old parallel algorithm.*

---

## 1 INTRODUCTION

The finite element (FE) method is widely used to solve and optimize any type of engineering problem. Computationally demanding and complex engineering problems composed of several thousand degrees of freedom are not uncommon anymore, especially when performing assessments with nonlinear dynamic analysis of reinforced concrete (RC) structures such as bridges, nuclear reactor and high-rise buildings that foresee the discretization of the concrete domain through isoparametric hexahedral elements and the reinforcement mesh with embedded rod or beam FEs. This modeling approach is known as 3D detailed approach [1-2], where embedded rebar macro-elements are found within the hexahedral mesh.

A search procedure is required to be performed to find the intersection of the macro-elements [3] with the hexahedral mesh (Fig. 1), to allocate the embedded rebar elements found within each hexahedral element. This procedure can be time consuming for large-scale models that consist of millions of embedded rebar elements. An efficient method for the generation of embedded reinforcement mesh was proposed by Markou and Papadrakakis [4] and parallelized in [5]. This work extends the algorithm proposed in [5], where the computational distribution is optimized.

## 2 EMBEDDED REBAR MESH GENERATION

Barzegar and Maddipudi [6] proposed the numerical method for the allocation and generation of embedded rebars inside hexahedral elements, which was an extension of the work performed by Elwi and Hrudey [7]. According to the hexahedral mesh, the standard Barzegar and Maddipudi [6] method is performed for cases of non-prismatic hexahedral elements, to allocate the natural coordinates of the corresponding virtual node. A point P1 with global coordinates  $(x, y, z)_{P1}$  on the initial rebar mesh (Fig. 1), is contained in a given concrete element if its natural coordinates  $\xi_{P1}, \eta_{P1}, \zeta_{P1}$  satisfy the following constraint:

$$|\xi_{P1}, \eta_{P1}, \zeta_{P1}| \leq 1 \quad (1)$$

In this formulation the global coordinates  $(x, y, z)$  of a common point within a solid element can be expressed as:

$$\begin{Bmatrix} x \\ y \\ z \end{Bmatrix} = \begin{bmatrix} N & 0 & 0 \\ 0 & N & 0 \\ 0 & 0 & N \end{bmatrix} \begin{Bmatrix} x_i \\ y_i \\ z_i \end{Bmatrix} \quad (2)$$

where  $x_i, y_i, z_i$  are the global coordinate vectors of the hexahedral nodes and  $N$  represents the row vector of the displacement-shape functions.

$$\begin{Bmatrix} x \\ y \\ z \end{Bmatrix}_{P1} - \begin{bmatrix} N & 0 & 0 \\ 0 & N & 0 \\ 0 & 0 & N \end{bmatrix} \begin{Bmatrix} x \\ y \\ z \end{Bmatrix} = 0 \quad (3)$$

Given that the natural coordinates  $(\xi, \eta, \zeta)_{P1}$  are the roots of Eq. 3, a Newton-Raphson iterative procedure is required in order to compute the solution of the above equation as follows:

$$\begin{Bmatrix} \xi \\ \eta \\ \zeta \end{Bmatrix}_{P_1}^{n+1} = \begin{Bmatrix} \xi \\ \eta \\ \zeta \end{Bmatrix}_{P_1}^n + \begin{Bmatrix} \Delta \xi \\ \Delta \eta \\ \Delta \zeta \end{Bmatrix}_{P_1}^{n+1} \quad (4)$$

Figure 1. Embedded reinforcement in hexahedral concrete element [3].

Since,

$$\begin{Bmatrix} d\xi \\ d\eta \\ d\zeta \end{Bmatrix} = (\mathbf{J}^T)^{-1} \begin{Bmatrix} dx \\ dy \\ dz \end{Bmatrix} \quad (5)$$

where  $\mathbf{J}$  is the Jacobian matrix, the incremental natural coordinates can then be computed from Eq. 6.

$$\begin{Bmatrix} \Delta \xi \\ \Delta \eta \\ \Delta \zeta \end{Bmatrix}_{P_1}^{n+1} = (\mathbf{J}^{nT})^{-1} \left[ \begin{Bmatrix} x \\ y \\ z \end{Bmatrix}_{P_1} - \begin{bmatrix} N^n & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & N^n & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & N^n \end{bmatrix} \begin{Bmatrix} x \\ y \\ z \end{Bmatrix} \right] \quad (6)$$

with

$$\mathbf{J}^n = \mathbf{J}(\xi^n, \eta^n, \zeta^n); \quad N^n = N(\xi^n, \eta^n, \zeta^n).$$

The mesh generation method proposed by Barzegar and Maddipudi [6] was found to be hindered with additional computational demand, however, this computational demand was reduced and optimized within [3] by implementing a geometric constraint that decreases unnecessary searches of intersection points. Furthermore, the algorithm was further integrated by determining if a hexahedral element is a parallelepiped or not. The proposed mesh generation procedure [3] was then parallelized in [5] as shown in Fig. 2.

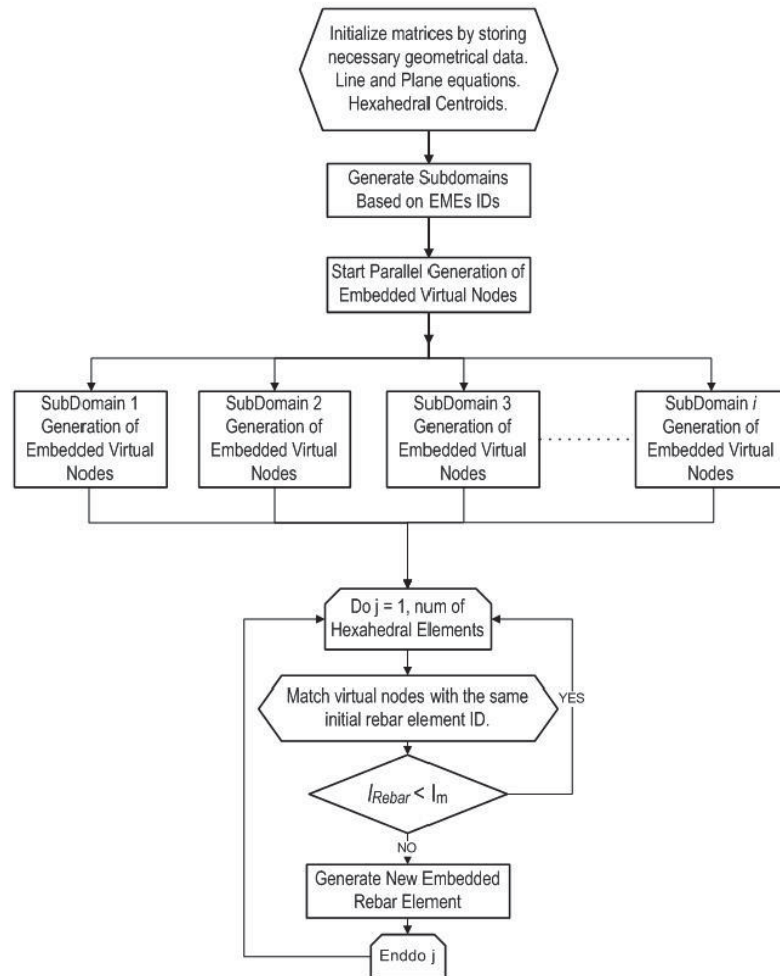

Figure 2. Flow chart of the embedded rebar mesh generation procedure [5].

This research work foresees the development of a parallel algorithm to improve the computational performance and efficiency of the algorithm shown in Fig. 2 for the large-scale embedded rebar mesh generation process.

### 3 PARALLEL PROCESSING METHODS AND TECHNIQUES

Engineering and scientific computing methods have significantly evolved over the past two decades, with the use of graphic processing units (GPU) in cooperation with a central processing unit (CPU). GPU-accelerated computing has become more popular due to its advanced features related to its parallel architecture, as well as, its capabilities on handling multiple problems simultaneously. Nevertheless, the use of GPUs is constrained from the need of customizing the build according to the hardware at hand. Furthermore, the appearance of the multicore processors brings about an important turning point in programming practices, especially with FE applications.

Fernández et al. [8] presented a new alternate way to formulate the finite element method (FEM) for parallel processing based on the solution of single mesh elements called FEM-SES. This method decouples the solution of a single element from the whole mesh, therefore, exposing parallelism at the element level. Each element solution is then superimposed node-wise using a weighted sum over the concurrent nodes. The research study performed by Fernández et al. [8] showed results up to 111 times faster than the results obtained on classic FEM problems.

Stavroulakis et al. [9] investigated a GPU domain decomposition solution for the spectral stochastic FEM. Within this research work they demonstrate the benefits achieved with the exploitation of the GPU capabilities, where they addressed problems where the solution of the FE algebraic equations was performed with the dual domain decomposition method by implementing specifically tailored preconditioners. This research concluded a significant enhancement of the spectral stochastic FEM, as well as the consumed energy efficiency achieved by this methodology.

Several other researchers [10-14] used parallel processing methods, introducing the basics of implementing parallel processing algorithms enhancing the efficiency and decrease the computational demand of FE software. The only research work found on parallel embedded rebar mesh generation was presented by [5] which is the work that will be used herein in proposing an improved parallel embedded rebar mesh generation framework. The main objective is to significantly improve the scalability and overall computational efficiency of the parallel embedded rebar mesh generation procedure.

#### 4 PROPOSED PARALLEL ALGORITHM

The proposed parallel algorithm is implemented within the research software, Reconan FEA [15]. The initial parallel framework was discussed and tested within [5], by analysing a NuScale reactor building that was investigated in Markou and Filippo [16]. This RC building was discretized with 8-noded hexahedral elements as it is going to be discussed in the next section.

The proposed parallel algorithm suggests a new computational load distribution process that calculates the computational load that will be assigned to each core prior to the mesh generation. The initial parallel algorithm foresaw the division of the number of embedded macro-elements into equal numbers based on their ID. This caused the unequal computational load distribution not allowing the embedded rebar mesh generation procedure to be performed in a computationally optimum manner, especially in cases where the macro-element lengths had significant differences within the model.

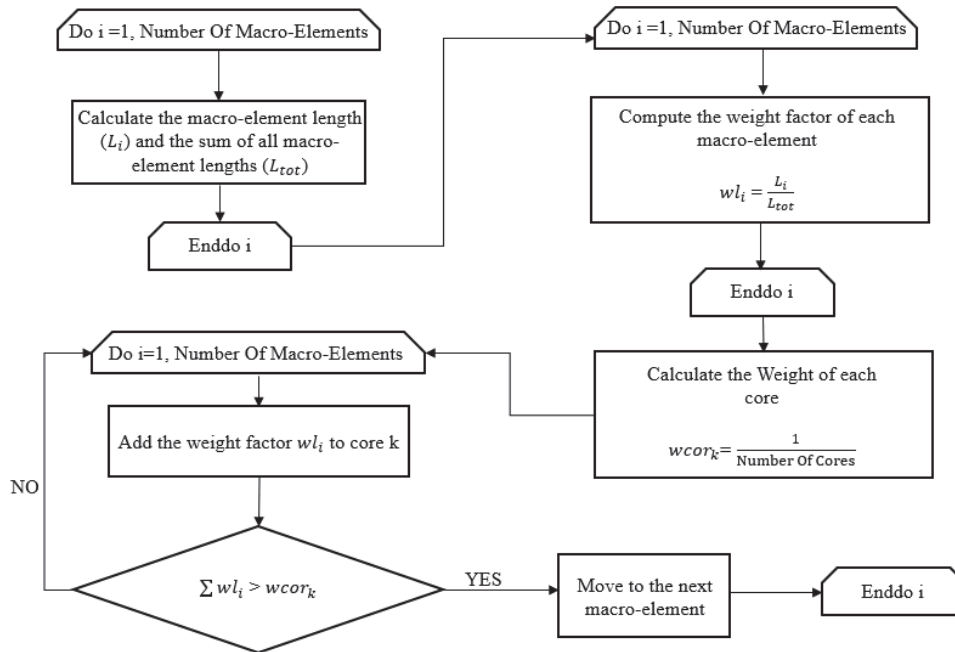

Figure 3. Flowchart for the proposed parallel algorithm.

An improved computational load distribution algorithm was developed for the needs of this research study that is performed based on the geometrical features of the embedded macro-elements found within the mesh. As it can be seen in Fig. 3, the proposed algorithm foresees the computation of the length of each macro-element  $L_i$ , while computing the total length of all macro-elements  $L_{tot}$  found within the mesh. A weight factor  $wl_i$  is computed for each macro-element, which equals to the length of the macro-element  $L_i$  divided by the total macro-elements' length:

$$L_{tot} = \sum_{j=1}^{num.elem.} L_j \quad (7)$$

$$wl_i = L_j / L_{tot} \quad (8)$$

Following the calculation of the weight factor  $wl_i$ , the computation of the weight factor  $wcor_k$  is computed for each core as shown in Fig. 3. This weight factor determines the total length of macro-elements that will be assigned to core  $k$ . Therefore, the macro-elements are divided and assigned to each core according to the overall length of the macro-elements that is directly connected to the performed calculations during the search of embedded rebar elements. The longer the macro-element is, the larger the number of hexahedral intersections, thus the larger the calculations required for the allocation of the virtual embedded rebar nodes.

## 5 REINFORCED CONCRETE MODEL

The NuScale reactor building, developed and studied in [16] is analysed for the needs of investigating the numerical response of the proposed parallel algorithm. This RC model shown in Fig. 4 has a total length of 75.25 m, a width of 30 m and a maximum height of 39.55 m. The FE framing system of the NuScale model was discretized with 181,076 8-noded isoparametric hexahedral elements as it can be seen in Fig. 4. Additionally, to decrease the mesh construction procedure, very long embedded macro-elements were used (up to 75 m in length, where the shortest macro-elements had 0.5 m length). The embedded macro-element mesh can be seen in Fig. 5 as it was developed by Markou and Filippo [16]. It should be noted that this structure has a total of 177,504 embedded macro-elements, where after the execution of the embedded rebar mesh generation procedure, a total of 2,703,251 embedded rebar finite elements are created within the final FE numerical model.

Figure 4: NuScale reactor building discretized with 8-noded isoperimetric hexahedral FEs.

Figure 5. Macro-elements of the NuScale reactor building.

## 6 NUMERICAL INVESTIGATION OF THE PROPOSED ALGORITHM

The numerical performance of the proposed algorithm was investigated through the use of a 12-core computer, with 4.2 GHz per core computational processing unit. This investigation foresaw the execution of 66 analyses of the NuScale reactor building presented above, in generating the embedded rebar elements. It should be noted at this point that 3 analyses were performed for each solution case using the proposed and the old parallel algorithms by assuming different number of cores, ranging from 2 to 12. When performing the analysis in a serial manner (1 core), the rebar generation computational time equals to 176.93 min. The results obtained from the parallel embedded rebar mesh generations can be seen in Fig. 6.

Figure 6: Algorithmic performance results for different number of cores when using the old and new algorithm.

As it can be depicted from Fig. 6, the computational time decreases as the number of cores increases, where the proposed distribution algorithm significantly improved the efficiency of the embedded rebar mesh generation procedure. When the number of cores used to solve the problem is set to 2, the proposed algorithm manages to achieve a 33.2% computational time decrease compared to the old algorithm. Furthermore, it is easy to observe that the new proposed algorithm decreased the computational demand from 104.69 minutes to 31.22 minutes when using 12 cores (see Table 1), which makes the proposed algorithm 3.4 times faster than the old one. As shown in Table 1, the scalability also improves when the number of cores used to solve this problem increases, when the proposed and the old algorithms are compared. In

addition to that, the proposed algorithm manages to decrease the total embedded rebar mesh generation time by 5.7 times when using 12 cores compared to the solution with 1 core.

Table 1: Computational time for each parallel analysis with the old and new algorithm.

	Number of cores										
	2	3	4	5	6	7	8	9	10	11	12
Old Algorithm parallel time (min)	136.10	121.63	114.14	112.81	106.44	109.15	107.59	103.72	102.39	100.76	104.69
New Algorithm parallel time (min)	90.91	78.37	53.26	49.82	49.80	40.11	37.56	35.25	31.52	32.91	31.22
Computational Time Decrease (%)	33.20	35.57	53.34	55.84	53.22	63.26	65.09	66.02	69.21	67.33	70.18

## 7 CONCLUSIONS

A newly developed and improved distribution load algorithm for parallel processing was presented and numerically investigated through the use of a NuScale reactor building model, consisting a total of 2,703,251 embedded rebar elements. The proposed algorithm took into account the length of each embedded macro-element utilizing a macro-element weight factor to distribute the computational load evenly to each core. Therefore, the distribution of the computational demand was performed based on the total macro-element length sent to each core and not based on the number of embedded macro-elements assigned to each core.

According to the numerical findings obtained from 66 analyses that foresaw the use of different number of cores, it was concluded that the proposed algorithm yielded a significant computational efficiency, allowing the embedded rebar mesh generation procedure to become up to 3.4 times faster compared to the performance of the older parallel algorithm [5].

Currently, the proposed algorithm is parametrically investigated through the use of more large-scale models, such as wind turbine structures, high-rise buildings and bridges. Furthermore, Reconan FEA has been integrated and is now been tested on a high-performance computer which has 40 cores per node. Future research work will investigate more computational load distribution approaches that will further optimize the numerical performance and scalability of the developed embedded rebar mesh generation procedure.

**Keywords:** Structural Dynamics, Random Matrices, Uncertainty Modelling, Component Mode Synthesis, Finite Element Method, Monte Carlo Simulation

**Abstract.** *Representation of random uncertainties in the context of reduced order models is addressed in this article. Traditional strategies are generally based on the description of non-deterministic features by random fields or parameters. Extraction of statistical properties of interest is achieved via a costly direct Monte Carlo simulation (MCS). While dynamic substructuring and reduction techniques can alleviate the impractical computational requirements of these methods, propagation of the physical space uncertainty characterisation into a condensed model is nontrivial. An explicit definition of random reduced substructural mass and stiffness poses an alternative. However, such a technique must yield samples that preserve certain mathematical properties of the nominal matrices. Following this paradigm, a recent approach, permitting the robust construction of  $2 \times 2$  block-partitioned, nonnegative definite Hermitian matrices is adopted herein. It employs a formulation relying on generalised Schur complements and random unitary matrices. Unlike other existing schemes, the sampling of component-level off-diagonal matrix blocks is an inherent feature of this method. Thus, it also preserves the blockwise mass and stiffness sparsity pattern of the global component mode synthesis (CMS) model. In this paper, an improved formulation allowing strict rank preservation and more efficient sampling is laid out. The proposed technique is compared against parametric MCS for the case of a satellite structure subjected to a non-uniform pressure excitation. A simulation speed-up of approximately 3 orders of magnitude is achieved, while a solid agreement with the benchmark solution is observed for the prediction of structural response variability.*

## 1 INTRODUCTION

Irrespectively of the level of detail of a mechanical system's mathematical model, deterministic descriptions are bound to provide only a partial insight into its actual physical behaviour. Uncertainty is introduced through various paths, such as non-ideal materials, geometric approximations and random boundary conditions. The description and quantification of such non-deterministic behaviour is central to the field of stochastic structural mechanics, reviewed in [1, 2, 3]. Contemporary techniques fall into a few major categories, as follows.

Probabilistic structural analysis (PSA) treats uncertain model properties as independent random variables, whose mean and variance are estimated a priori. Barring perturbation theory, which is not well-suited to representing high coefficients of variation (COVs) [2], MCS is traditionally performed [4]. Upon generating a sufficiently large number of realisations of the random structure, each resultant deterministic case is solved. Quantities of interest are then computed by statistical manipulation of the results. Direct MCS application is comparatively straightforward, and its predictions tend capture the real structure's stochastic behaviour well. Thus other schemes are often validated against PSA, e.g. for spacecraft design and analysis [5, 6].

The parameter space characterisation of PSA is often viewed as oversimplified. Logically, an uncertain physical quantity would not deviate uniformly from some mean value over its whole domain. The basis of the stochastic finite element method (SFEM) [7, 8] is formed by the inclusion of spatial variability, which gives rise to random fields. They are expressed via field variables that represent spatial fluctuation and probabilistic behaviour. A challenging aspect of SFEM is that a discrete computational domain has to be prescribed for the random fields over the application geometry. In contrast to SFEM's academic popularity, utilisation in commercial software remains currently limited, with notable exceptions discussed in [9, 10].

A solid practical argument against the aforesaid techniques is the estimation of a system failure probability  $p_F$ . Conventional MCS demands a number of analyses of order  $1/p_F$ , such that very low-probability samples containing failure events can be extracted from the population. With the exception of simple problems, MCS is clearly infeasible. The issue is addressed by a class of so-called variance reduction methods, comprised of two prominent advancements - subset simulation [11] and line sampling [12]. Both exhibit comparable performance for certain high-complexity problems, with the evaluation of  $p_F$  taking hundreds of samples, instead of millions for the direct MCS [13, 5, 6].

In contrast to other methods, the popular nonparametric probabilistic approach of Soize [14] constructs a non-deterministic model without random variables or fields. It relies on random matrix theory and the maximum entropy principle, which stems from information theory. The objective is to build a stochastic model that maximises uncertainty within available constraints. Random structural matrices are obtained from known deterministic ones, with only a single parameter responsible for specifying their dispersion. Statistical moments of the responses are calculated by standard MCS. An updated version of the approach [15] permits the separate treatment of modelling errors and system parameter uncertainties.

Shifting the perspective to practicality of analysis and computational efficiency, splitting complex FE representations into smaller parts is commonplace [16], c.f. Figure 1. In CMS, each component is projected onto a suitable basis in a generalised degree of freedom (DOF) space, yielding greatly reduced problem dimensions. The condensed system is then synthesised, i.e. reassembled. Unsurprisingly, CMS is widely adopted in the space industry, where FE models can surpass millions of DOFs, becoming impractical to handle. The classic Craig-Bampton

Figure 1: Substructuring visualisation: (a) partitioning, (b) definition of component interface connections

(CB) method [17] remains the prevalent CMS technique, with multiple improved versions also available [18, 19]. Additional modern contributions to the field include automated substructuring [20], exploring non-standard projection bases, different interface reduction schemes and combinations thereof [21, 22, 23].

As the ongoing growth in computing resources has been matched by FE model complexity, closing the gap between stochastic analysis and reduction techniques remains highly desirable. Some modal approaches such as [24] have been delineated, normally restricted to a CB reduction [25, 26]. However, a distinct lack of methods appropriate for dealing with random uncertainties on a substructural level in a generic CMS setting is observed. The nonparametric probabilistic approach marks a partial exception, but it does not preserve the blockwise sparsity of CMS representations. In brief, robustly constructing individual random blocks of substructural matrices is not tractable with existing methods, especially for off-diagonal partitions.

In the present article, these issues are dealt with by a mathematical formulation specifically derived for the construction of blockwise random  $2 \times 2$  nonnegative definite matrices of given rank. An early rendition of the method was presented in [27], indicating promising efficiency and accuracy. Here, an amended version is laid out, benefiting from a simpler, yet mathematically more rigorous definition. Verification against direct MCS for a practical benchmark case of a Craig-Bampton reduced spacecraft is demonstrated.

## 2 STOCHASTIC CMS THEORETICAL FORMULATION

### 2.1 General notation

Let us first establish the notation employed throughout the rest of the article. Boldface upper and lower case letters are used for matrices and vectors, respectively. We denote the conjugate transpose of a matrix  $\mathbf{A} \in \mathbb{C}^{m \times n}$  by  $\mathbf{A}^*$  and its pseudoinverse by  $\mathbf{A}^+$ . For better readability, the shorthand style  $\mathbf{A}^{+*}$  is used in place of the compound operation  $(\mathbf{A}^+)^*$ , equivalent to  $(\mathbf{A}^*)^+$ . The (possibly generalised) Schur complement of  $\mathbf{X}$  in  $\mathbf{A}$  is denoted by  $\mathbf{A}/\mathbf{X}$ . We further use  $\mathbf{A} \succ \mathbf{0}$  and  $\mathbf{A} \succeq \mathbf{0}$  to specify that  $\mathbf{A} \in \mathbb{C}^{n \times n}$  is strictly positive definite or positive semi-definite (PSD), respectively.

The  $i$ -th eigenvalue of  $\mathbf{A} \in \mathbb{C}^{n \times n}$  is written as  $\lambda_i(\mathbf{A})$ , with ordering  $\lambda_1 \geq \dots \geq \lambda_n$ . Analogously,  $\sigma_i(\mathbf{A})$  is  $i$ -th singular value of  $\mathbf{A} \in \mathbb{C}^{m \times n}$ , where  $\sigma_1 \geq \dots \geq \sigma_{\min\{m,n\}}$ . Lastly, the tilde accent indicates non-deterministic quantities, e.g.  $\tilde{x}$  is a random variable  $x$ . The topics in linear algebra relevant to this paper are covered in [28, 29].

## 2.2 Prerequisites

Consider the generalised eigenvalue problem (GEP):

$$(\mathbf{K} - \lambda_i \mathbf{M})\phi_i = 0, \quad i = \{1, \dots, n\} \quad (1)$$

with  $i$ -th structural mode  $\phi_i$  and discrete stiffness and mass  $\mathbf{K}$ ,  $\mathbf{M}$ , typically both real in FEM. Unless  $\mathbf{K}$ ,  $\mathbf{M} \succeq \mathbf{0}$ , i.e. they are at least positive semi-definite, the GEP can be shown to have negative eigenvalues. This translates to complex structural natural frequencies, which are given by  $\omega_i^2 = \lambda_i(\mathbf{K}, \mathbf{M})$ . Consequentially,  $\phi_i \in \mathbb{R}$  does not hold either. In order to circumvent this issue, the random matrices  $\tilde{\mathbf{K}}$ ,  $\tilde{\mathbf{M}}$  that we will construct must be strictly PSD.

To avoid superfluous notation, let us introduce an  $n \times n$  Hermitian matrix  $\mathbf{G}$  and its random counterpart  $\tilde{\mathbf{G}}$ , with their  $2 \times 2$  block partitioning

$$\mathbf{G} = \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{D} \end{bmatrix}, \quad \tilde{\mathbf{G}} = \begin{bmatrix} \tilde{\mathbf{A}} & \tilde{\mathbf{B}} \\ \tilde{\mathbf{B}}^* & \tilde{\mathbf{D}} \end{bmatrix} \quad (2)$$

as placeholders for any substructural or global  $\mathbf{M}$  or  $\mathbf{K}$ . Usually, free-free configuration FE models' mass and stiffness matrices have nonempty nullspaces. These correspond to the rigid body modes of the structure, thus are normally subspaces whose dimension is 6, i.e. equal to the number of global spatial degrees of freedom in 3D. The nullspace dimension of  $\tilde{\mathbf{G}}$  with respect to  $\mathbf{G}$  is therefore a further mathematical feature that should be respected. Altering the number of rigid body modes in realisations of the random structure would clearly be unphysical.

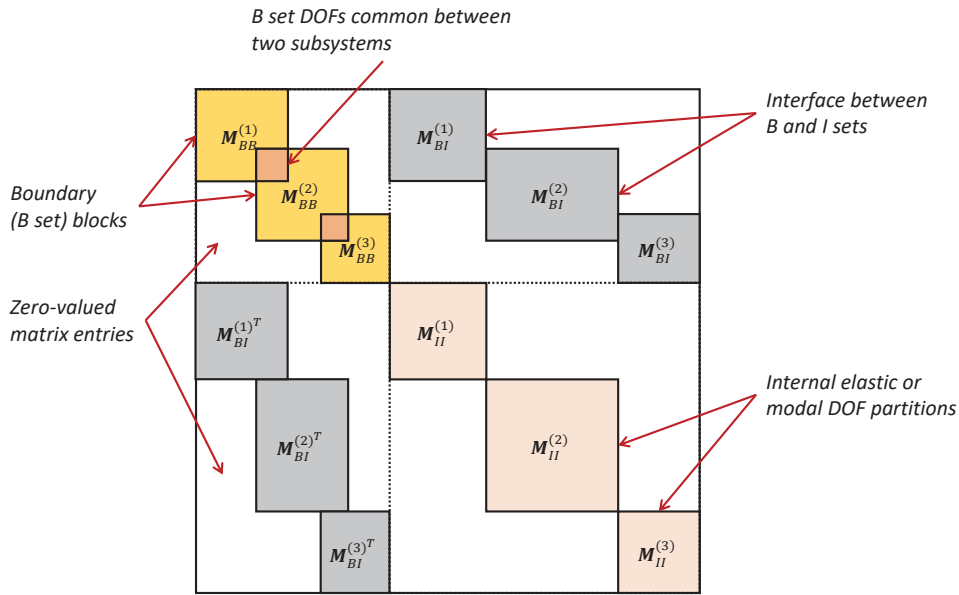

Figure 2: Form of a partitioned and DOF-ordered mass matrix for 3 subsystems

## 2.3 Mathematical framework

In dynamic substructuring problems the  $2 \times 2$  block matrix format naturally occurs on both local and global system levels, owed to the separation of boundary and internal elastic DOFs. This is illustrated on Figure 2, which depicts the blockwise sparse structure of a mass matrix in primal assembly. Exploiting this logical division would be particularly attractive for describing

subcomponent variability, especially in a reduced model context. The main obstacle lies in finding an interdependency within the global matrix structure, such that the permissible range of values for any of its blocks can be specified as some function of the remaining ones. For instance, how can the random partition  $\tilde{\mathbf{B}}$  be characterised by the submatrices  $\mathbf{A}$  and  $\mathbf{D}$ , such that for any possible realisation of  $\tilde{\mathbf{B}}$ , the conditions of Section 2.2 are met.

Note that the detailed proofs of ensuing key statements are fairly lengthy and thus beyond the scope of this paper. It is possible to derive the following fundamental result:

**Theorem 1** (Nonnegative definiteness). *For a Hermitian matrix  $\mathbf{G} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{D} \end{pmatrix}$ ,  $\mathbf{G} \succeq \mathbf{0}$  if and only if*

- (a) *all singular values  $\sigma_i(\mathbf{L}_A^+ \mathbf{B} \mathbf{L}_D^{+*}) \leq 1$ , where  $\mathbf{A} = \mathbf{L}_A \mathbf{L}_A^*$  and  $\mathbf{D} = \mathbf{L}_D \mathbf{L}_D^*$*
- (b)  *$\text{range}(\mathbf{B}) \subseteq \text{range}(\mathbf{A})$*
- (c)  *$\text{range}(\mathbf{B}^*) \subseteq \text{range}(\mathbf{D}^*)$*

Broadly speaking, Theorem 1 can be proven by calling upon the generalised Schur complement condition, which states that  $\mathbf{G} \succeq \mathbf{0}$  if and only if

$$\mathbf{A} \succeq \mathbf{0}, \mathbf{D} - \mathbf{B}^* \mathbf{A}^+ \mathbf{B} \succeq \mathbf{0}, (\mathbf{I} - \mathbf{A} \mathbf{A}^+) \mathbf{B} = \mathbf{0} \quad (3)$$

in conjunction with a technical lemma

**Lemma 2.** *For a Hermitian  $\mathbf{T}$  a necessary but not sufficient condition for  $\mathbf{S} \mathbf{T} \mathbf{S}^* \succeq \mathbf{0}$  is  $\text{range}(\mathbf{V}_n) \cap \text{range}(\mathbf{S}^*) = \{\mathbf{0}\}$ , where  $\mathbf{V}_n$  is the matrix of eigenvectors of  $\mathbf{T}$  with negative associated eigenvalues.*

For the strict case, which corresponds to a matrix  $\mathbf{G}$  with a trivial nullspace, e.g. the mass or stiffness of a FE model constrained in space, we have

**Corollary 3.** *Given a Hermitian matrix  $\mathbf{G} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{D} \end{pmatrix}$ ,  $\mathbf{G} \succ \mathbf{0}$  if and only if  $\sigma_i(\mathbf{L}_A^{-1} \mathbf{B} \mathbf{L}_D^{-*}) < 1$ , where  $\mathbf{A} = \mathbf{L}_A \mathbf{L}_A^*$  and  $\mathbf{D} = \mathbf{L}_D \mathbf{L}_D^*$ .*

Attention is drawn to the fact  $\mathbf{L}_A$  and  $\mathbf{L}_D$  may be any possible factors of the diagonal blocks of  $\mathbf{G}$ . For a strictly positive definite block, a Cholesky decomposition can be taken. Generally, at least one of  $\mathbf{A}$ ,  $\mathbf{D}$  may be singular. We can use the singular value decompositions (SVDs)

$$\mathbf{L}_A = \mathbf{Q}_A \Sigma_A^{1/2} \mathbf{X}_A^*, \quad \mathbf{L}_D = \mathbf{Q}_D \Sigma_D^{1/2} \mathbf{X}_D^* \quad (4)$$

where  $\mathbf{L}_A \mathbf{L}_A^* = \mathbf{Q}_A \Sigma_A \mathbf{Q}_A^*$  is the spectral decomposition of  $\mathbf{A}$ ,  $\mathbf{X}_A^*$  is an arbitrary unitary matrix, and  $\mathbf{L}_D$  is obtained analogously.

We turn our attention to the construction of blockwise stochastic matrices. Initially, we consider only the off-diagonal partitions  $\mathbf{B}$  of  $\mathbf{G}$ . Using Eq. (4), let  $\mathbf{Z}$  and its SVD be given by

$$\mathbf{Z} = \mathbf{L}_A^+ \mathbf{B} \mathbf{L}_D^{+*} = \mathbf{U}_Z \Sigma_Z \mathbf{V}_Z^* \quad (5)$$

Now, take  $\tilde{\Sigma}_Z \in \mathbb{R}$  to be a random diagonal matrix of the size and rank of  $\Sigma_Z$ , with nonzero elements not exceeding unity. Then

$$\tilde{\mathbf{Z}} = \tilde{\mathbf{U}}_Z \tilde{\Sigma}_Z \tilde{\mathbf{V}}_Z^* \quad (6a)$$

$$\tilde{\mathbf{B}} = \mathbf{L}_A \tilde{\mathbf{Z}} \mathbf{L}_D^* = \mathbf{L}_A \tilde{\mathbf{U}}_Z \tilde{\Sigma}_Z \tilde{\mathbf{V}}_Z^* \mathbf{L}_D^* \quad (6b)$$

where  $\tilde{\mathbf{U}}_Z$  and  $\tilde{\mathbf{V}}_Z$  are completely unrestricted random unitary matrices. Crucially, it holds that

**Proposition 4.** Let  $\mathbf{G} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B}^* & \mathbf{D} \end{pmatrix}$  be a Hermitian PSD matrix,  $\tilde{\mathbf{B}} = \mathbf{L}_A \tilde{\mathbf{Z}} \mathbf{L}_D^*$  be random blocks, as per Eq. (6), and  $\tilde{\mathbf{Z}}$  be any possible matrix abiding to Eq. (5) whose singular values do not exceed unity. Then the domain of  $\tilde{\mathbf{G}} = \begin{pmatrix} \mathbf{A} & \tilde{\mathbf{B}} \\ \tilde{\mathbf{B}}^* & \mathbf{D} \end{pmatrix}$  coincides with the set of all nonnegative definite matrices with constant diagonal blocks  $\mathbf{A}$ ,  $\mathbf{D}$ .

A proof of Proposition 4 hinges on the assertion that swapping  $\mathbf{B}$  with its random counterpart still fulfils all conditions of Theorem 1. Provided that  $\mathbf{A}$  and  $\mathbf{D}$  are kept fixed, the transition from  $\mathbf{Z}$  to  $\tilde{\mathbf{Z}}$  is facilitated entirely by  $\tilde{\mathbf{B}}$ . The construction of  $\tilde{\mathbf{B}}$  is hence 'uncoupled' from that of  $\tilde{\mathbf{A}}$ ,  $\tilde{\mathbf{D}}$ . Regarding these partitions, which are square and PSD, methods such as eigenvalue perturbation or the nonparametric variability approach can be applied. Thereby only the more involved case of  $\tilde{\mathbf{B}}$  was discussed here. Evaluating realisations of  $\tilde{\mathbf{G}}$  can be done by sampling  $\tilde{\mathbf{A}}$ ,  $\tilde{\mathbf{D}}$ , then  $\tilde{\mathbf{B}}$  sequentially.

So far we have shown that Eq. (6) describes all possible matrices  $\tilde{\mathbf{B}}$  that satisfy Theorem 1 for given  $\mathbf{A}$ ,  $\mathbf{D}$ . Now, nullspace dimension controllability can be addressed

**Theorem 5 (Rank).** The rank of  $\tilde{\mathbf{G}}$  is invariant with respect to unitary transformations of  $\mathbf{L}_A^+ \mathbf{B} \mathbf{L}_D^{+*}$  and if  $\text{null}(\mathbf{L}_A) = \text{null}(\mathbf{L}_D) = \{\mathbf{0}\}$  it is exactly equal to  $\text{rank}(\mathbf{I} - \tilde{\Sigma}_Z^* \tilde{\Sigma}_Z)$ .

Rephrasing Theorem 5, any unitary transformation of  $\mathbf{L}_A^+ \mathbf{B} \mathbf{L}_D^{+*}$  is, both mathematically and for all pragmatic intents and purposes, equivalent to sampling  $\tilde{\mathbf{U}}_Z$  and  $\tilde{\mathbf{V}}_Z$  in Eq. (6a). Furthermore,  $\mathbf{L}_A$  and  $\mathbf{L}_D$  can be ensured to have a trivial nullspace by taking a standard truncated SVD in Eq. (4), by discarding all singular vectors corresponding to zero singular values. In practice if, for instance,  $\mathbf{A}$  is degenerate,  $\mathbf{L}_A$  would be rectangular, with as many 'missing' columns as is the rank deficiency of  $\mathbf{A}$ . Of course,  $\text{rank}(\mathbf{A}) = \text{rank}(\mathbf{L}_A)$  still holds. Note that the validity of all preceding assertions only requires the existence of  $\mathbf{L}_A$ ,  $\mathbf{L}_D$ , and is invariant with their shape.

Finally,  $\text{rank}(\tilde{\mathbf{G}}) = \text{rank}(\mathbf{I} - \tilde{\Sigma}_Z^* \tilde{\Sigma}_Z)$  postulates that retaining the number of ones on the diagonal of  $\Sigma_Z$  unaltered when sampling  $\tilde{\Sigma}_Z$  is necessary and sufficient to ensure  $\dim(\text{null}(\mathbf{G})) = \dim(\text{null}(\tilde{\mathbf{G}}))$ .

## 2.4 An appropriate model for the random unitary matrices

A sensible definition of  $\tilde{\mathbf{U}}_Z$  and  $\tilde{\mathbf{V}}_Z$  through which the dispersion of  $\tilde{\mathbf{B}}$  is constrained and can be regulated is vital. Throughout Section 2.3,  $\mathbf{G}$  was assumed complex, but all arguments made trivially ensue for the special case  $\mathbf{G} \in \mathbb{R}$ , pertinent to structural FEM. Thereby we seek to construct stochastic orthogonal  $\tilde{\mathbf{U}}_Z, \tilde{\mathbf{V}}_Z \in \mathbb{R}$ . The approach suggested here is to compute their eigendecompositions

$$\mathbf{U}_Z = \mathbf{Q}_U \mathbf{\Lambda}_U \mathbf{Q}_U^*, \quad \mathbf{V}_Z = \mathbf{Q}_V \mathbf{\Lambda}_V \mathbf{Q}_V^* \quad (7)$$

and retain the bases  $\mathbf{Q}_U, \mathbf{Q}_V$ , resulting in

$$\tilde{\mathbf{U}}_Z = \mathbf{Q}_U \tilde{\mathbf{\Lambda}}_U \mathbf{Q}_U^*, \quad \tilde{\mathbf{V}}_Z = \mathbf{Q}_V \tilde{\mathbf{\Lambda}}_V \mathbf{Q}_V^* \quad (8)$$

The eigenvalues of orthogonal matrices lie on the unit circle and appear in either complex conjugate pairs or are equal to one. The diagonal matrices  $\tilde{\mathbf{\Lambda}}_U, \tilde{\mathbf{\Lambda}}_V$  in Eq. (8) therefore adhere to the form

$$\tilde{\mathbf{\Lambda}}_U = \text{diag}(e^{i\tilde{\theta}_U}), \quad \tilde{\mathbf{\Lambda}}_V = \text{diag}(e^{i\tilde{\theta}_V}) \quad (9)$$

where  $i$  is the imaginary unit,  $\tilde{\theta}_U, \tilde{\theta}_V$  are random angle vectors. It can be validated that realisations of  $\tilde{\mathbf{U}}_Z, \tilde{\mathbf{V}}_Z$  are real and orthogonal, provided the complex conjugate pairs in  $\tilde{\theta}_U, \tilde{\theta}_V$  are kept unmodified with respect to  $\theta_U, \theta_V$ . Consequentially, for a non-deterministic orthogonal matrix

$\tilde{U}_Z$  of size  $n$ , only a random vector  $\tilde{\varphi}_U$  of length  $\lfloor \frac{n}{2} \rfloor$  needs to be sampled in order to evaluate a realisation of the corresponding  $\tilde{\theta}_U$ .

Observe that now  $\tilde{B}$ , as defined in Eq. (6b), is fully specified by  $\tilde{\theta}_U$ ,  $\tilde{\theta}_V$  (through  $\tilde{\varphi}_U$ ,  $\tilde{\varphi}_V$ ), and  $\tilde{\Sigma}_Z$  by

$$\begin{aligned}\tilde{B} &= L_A \tilde{U}_Z \tilde{\Sigma}_Z \tilde{V}_Z^* L_D^* \\ &= L_A Q_U \tilde{\Lambda}_U Q_U^* \tilde{\Sigma}_Z Q_V \tilde{\Lambda}_V^* Q_V^* L_D^*\end{aligned}\quad (10)$$

This construction poses several key benefits. Firstly, rank preservation of  $\tilde{G}$ , thus  $\tilde{M}$  or  $\tilde{K}$  is always guaranteed. Secondly, computation of realisations is easy, as only random vectors need to be sampled. Vectorised code implementations are also straightforward to write.

## 2.5 Comparison to the original technique and algorithmic complexity

In comparison to theory outlined above, the prototype of the random block matrix method, i.e. [27], employed

$$\tilde{U}_Z = \tilde{R}_A U_Z, \quad \tilde{V}_Z = \tilde{R}_D V_Z \quad (11)$$

where  $\tilde{R}_A$ ,  $\tilde{R}_D$  are sparse non-deterministic rotation matrices, composed of random Givens rotations. While it performed well in test cases, it is feasible to strictly prove that rank preservation, thus nullspace dimension of random mass and stiffness, is not guaranteed under certain conditions. The issue is solved in the present paper by the rank/shape constraints imposed on  $L_A$ ,  $L_D$  in Theorem 5. In fact, the original definition of  $\tilde{B}$  in Eq. (11) is now generalised by Eq. (6). Furthermore, Eqns. (8)-(10) provide means of prescribing  $\tilde{B}$  without introducing any auxiliary matrices that do not emerge naturally from decompositions of partitions of  $G$ .

Sampling submatrices of  $\tilde{G}$  is evidently of cubic complexity. The cost incurred by the updated Eq. (10) is very similar to the original method, c.f. [27]. It is worth pointing out that the decompositions  $L_K^{(k)}$  or  $L_M^{(k)}$  for the  $k$ -th component need to be computed only once. In addition, the number of DOFs in a subsystem's boundary or modal representations would typically be small, namely of order not exceeding  $10^3$ , either by design or due to the use of interface reduction. Due to the minimal size of the random blocks,  $O(n^3)$  complexity of the stochastic block matrix sampling does not impair overall efficiency. Per realisation, it is in-line with the cost of a plain CMS modal solution.

Referring to Figure 2, eqns. (8)-(10) would facilitate generation of non-deterministic interface blocks  $\tilde{M}_{BI}^{(k)}$  from factorisations of  $M_{BB}^{(k)}$  and  $M_{II}^{(k)}$ . Note that in this example, subsystems 1 and 3 do not share common DOFs.

## 3 METHOD VALIDATION

The methodology outlined in Section 2 was implemented in Matlab and benchmarked with a realistic test case, based on the SSTL300 spacecraft, shown in Figure 3. It is designed and built by Surrey Satellite Technology Limited (SSTL) and has external dimensions of 1370 mm  $\times$  850 mm  $\times$  1200 mm and mass of 300 kg.

A mock-up surface load was obtained from 50 superimposed plane wave sources, evenly distributed over a unit sphere, whose centre coincides with the geometric centre of the model. A diffuse sound field was emulated by sampling the wave phases from a uniform distribution between  $-\pi$  and  $\pi$ . Their amplitudes were extracted from a Gaussian distribution truncated to the interval  $[0, 2]$ , whose mean and variance were 1 and 0.5, respectively. The incident field

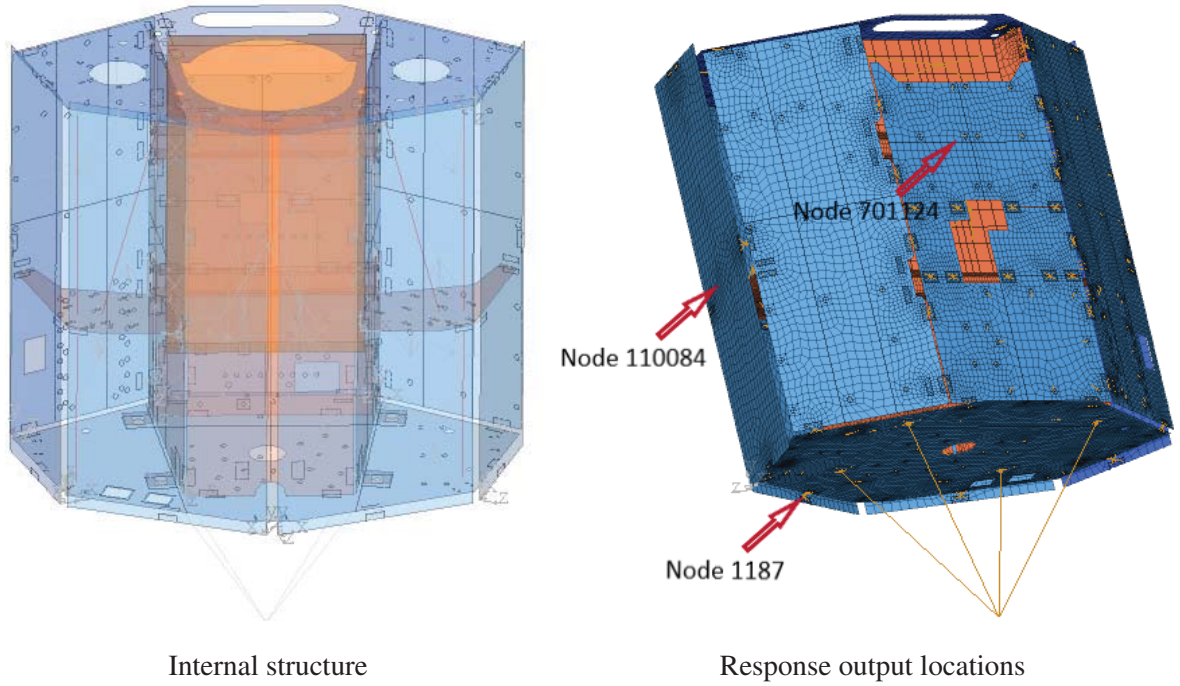

Figure 3: Stochastic CMS realistic test case: SSTL300 spacecraft

was evaluated at 200 frequency points, spaced logarithmically between 1 Hz and 1.5 kHz. It was subsequently used as direct excitation to the structure. Normally, elasto-acoustic coupling would be accounted for. Nevertheless, the aim of this test was solely to compare the stochastic CMS against a well-established numerical scheme for a complex model. Provided a good agreement between the two methods is observed, either would be similarly representative of any data acquired from physical tests.

Firstly, a direct Monte Carlo simulation was set up. Uncertain parameters in the model were approximated as normally distributed random variables. The concrete values used are given in Table 1, expressed in terms of COV, with  $\mu$  being the distribution mean. The selection of appropriate COVs has been thoroughly studied. Such investigations are widely available in literature, for instance in [5]. 500 realisations were sampled and solved for the MCS.

From a CMS perspective, the formulation delineated in Section 2 was applied to a standard Craig-Bampton reduction. The spacecraft was split into 10 subsystems, 9 of which were its main external panels. The latter were subjected to the aforesaid pressure excitation, whereas no loads were directly applied to the internal structure. An example is depicted in Figure 4. All component condensations included modes up to 2.5 kHz. As a preprocessing step, MSC Nastran was employed for producing the physical space structural and CB transformation matrices. It was further utilised for the modal solution of MCS realisations. The stochastic CMS was executed fully on in-house Matlab code.

Detailed component and global DOF set data is presented in Table 2. The equilibrium equation for the  $k$ -th condensed substructure is

$$\begin{bmatrix} \mathbf{M}_{bb}^{(k)} & \widetilde{\mathbf{M}}_{bm}^{(k)} \\ \widetilde{\mathbf{M}}_{mb}^{(k)} & \mathbf{I}_{mm}^{(k)} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}}_b^{(k)} \\ \ddot{\mathbf{u}}_m^{(k)} \end{bmatrix} + \begin{bmatrix} \mathbf{K}_{bb}^{(k)} & \mathbf{0} \\ \mathbf{0} & \widetilde{\mathbf{\Lambda}}_{mm}^{(k)} \end{bmatrix} \begin{bmatrix} \mathbf{u}_b^{(k)} \\ \mathbf{u}_m^{(k)} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_B^{(k)} + \mathbf{\Phi}_B^{(k)T} \mathbf{f}_I^{(k)} \\ \mathbf{\Phi}_I^{(k)T} \mathbf{f}_I^{(k)} \end{bmatrix} \quad (12)$$

where subscripts  $b$  and  $m$ , respectively, refer to the reduced boundary and internal elastic DOF sets and  $\mathbf{u}$  denotes displacements. The physical space forces are given by  $\mathbf{f}_B$  and  $\mathbf{f}_I$ . They are

	Non-structural mass	NSM	$0.10\mu$
Spring	Stiffness	$k_i$	$0.05\mu$
Point mass	Mass	$m$	$0.06\mu$
Damping	Modal value		const.

<sup>a</sup> Not applicable to the test case, or is described as a function of already defined values, e.g.  $G = \frac{E}{2+2\nu}$

projected onto Craig-Bampton mixed physical-modal coordinates through the typical transformation matrices  $\Phi_B$  and  $\Phi_I$ . The latter are a constraint mode matrix and a truncated eigenbasis, respectively. Conforming to the widely accepted normalisation, the modal mass is scaled to the identity matrix  $I_{mm}$ , hence modal stiffness  $\Lambda_{mm}$  is given by the square of each mode's respective natural frequency.

Table 2: DOFs per subsystem for the Craig-Bampton reduced and physical coordinate SSTL300 model

Subsystem	CB Reduction		Full model
	modal	boundary	physical
1	92	114	23202
2	97	114	15732
3	118	186	38066
4	79	72	19566
5	98	114	25488
6	37	24	6870
7	56	30	9714
8	37	24	6870
9	56	30	9714
10	359	366	82829
Total	1029	1074	244812
Reassembled	1029	540	243738

The stochastic off-diagonal mass terms,  $\widetilde{M}_{mb}^{(k)}$  were modelled and sampled according to Eqns. (8)-(10). Gaussian distributions with standard deviation of 0.3 radians and mean  $\varphi$  were assigned to the random angles  $\widetilde{\varphi}$ , whereas  $\widetilde{\Sigma}_z$  was kept constant. The component modal stiffnesses  $\widetilde{\Lambda}_{mm}^{(k)}$  were also normally distributed, with COVs of 0.1. A remark should be made that in general, the  $\widetilde{\Sigma}_z$  term exerts a relatively minor influence on the variance of the computed global solutions. Similarly to the direct MCS, 500 random model realisations were evaluated. This number was deemed reasonable for acceptable convergence of the first two statistical moments to be attained.

The results collected from the new stochastic CMS are plotted and compared against the direct MCS in Figure 5. The mean and  $\mu + 3\sigma$  response curves, equivalent to a 99.7% confidence interval, are plotted for either numeric scheme, along with the baseline deterministic solution. Overall, the predictions of the reduced-order stochastic method conform to the ones obtained by direct MCS. Examining the plots closely, it can be seen that the low-frequency range uncertainty is predicted to have slightly smaller variance compared to the MCS. However, the COVs chosen for this work were not based on an extensive parameter survey. It is expected that even better correlation against the MCS could be observed under some optimised strategy for designating variability level to the random substructures.

As a measure of the overall uncertainty prediction quality, a global linear correlation coefficient was computed for the statistical moments estimated by the new method against the MCS. This was done by averaging solution correlations over all output DOFs for the full frequency range. Coefficients of 0.95 and 0.93 were calculated for the mean and variance of the solutions,

respectively. Figure 5 is representative of these values.

Figure 5: Acceleration magnitude: (a) node 1187, z-axis,  $B$  set physical interface between two subsystems, (b) node 701124, x-axis,  $B$  set output location, not used as CMS subsystem connector, (c) node 1100884, y-axis,  $I$  set, response recovered from the CB solution

Regarding computational efficiency, the reduced-order scheme exhibited a clear advantage by taking approximately 0.8 s per realisation, against 302 s for the parametric approach. Note that the latter is pure solver CPU time and comprises less than half the wall-clock time per realisation when I/O operations are taken into account. In practice, this translates to an improvement factor of over 750. Furthermore, while a commercial solver was used for the direct MCS, the stochastic CMS was solved on code that could benefit from further optimisation. Overall, the new method provided nodal acceleration estimations close to the baseline solution, but with greatly improved performance and arguably ease of implementation.

## 4 CONCLUSIONS

Modelling of random uncertainties on a subsystem-level is addressed in this article. To that end, a method circumventing many of the usual restrictions associated with nonparametric techniques in a reduced-order model context was proposed. Namely, the component-level matrix structure naturally arising in CMS can be exploited to robustly define and sample random local mass and stiffness partitions. The foundation for the technique's mathematical definition was derived from the generalised Schur complement condition for nonnegative definiteness. Further extending the concept, a framework was provided for individual block sampling of  $2 \times 2$  random Hermitian matrices of fixed rank. A construction to adapt this theoretical basis to FEM structural matrices was provided. The proposed stochastic CMS technique was applied to a spacecraft structure subjected to acoustic excitation, and compared against parametric MCS. Reliable response predictions were recorded, whereas computational cost was reduced by close to 3 orders of magnitude.

## ACKNOWLEDGEMENTS

The author would like to thank Surrey Satellite Technology Limited for providing the spacecraft model used for this work.

### Abstract

*Riveted connections are the most common structural details of existing steel bridges. Due to the increase of traffic loads as respect to the conditions at their erection time, existing riveted bridges are usually characterized by structural deficiencies and prone to fatigue damages. Moreover, the structural inadequacies are often magnified by the presence of peculiar constructional defects (i.e. shank misalignment, forged head distortion), which induce local stress concentrations that further reduce the service life.*

*In this paper, the behaviour of riveted lap shear connections under static and cyclic actions is investigated by means of finite element (FE) simulations. The investigated connections are representative of typical geometries of the details of actual existing railway bridges. FE models were calibrated against the results of former tests drawn from literature. In addition, the FE models allowed at investigating the influence of constructional imperfections on the ultimate static and fatigue resistance and of the connections. In order to widen the parametric study, the following parameters are varied, namely: (i) number of rivets, (ii) diameter of rivet shank, (iii) thickness and width of the plates.*

**Keywords:** Lap shear connections, Fatigue, Riveted connections, Existing Steel Bridges, Finite Element Analysis.

---

## 1 INTRODUCTION

Riveted steel bridges represent the most common type of existing railway bridges in Italy [1]. The diffusion of this structural typology mainly developed between the XIX<sup>th</sup> century and the first half of the XX<sup>th</sup> century, after which the usage of hot-driven rivets gradually diminished owing to the introduction of high-strength bolts [2]. Therefore, existing riveted railway bridges in Italy are often characterized by an exceptionally long service life. This condition, in conjunction with the increase of traffic loads through the years, inevitably exposes such kind of structures to critical fatigue issues.

Moreover, the adopted technology for the implementation of hot-driven rivets (i.e. heat forging) can lead to peculiar structural imperfections which further reduce the structural service life. Indeed, the heating process brings the rivet base material to a plastic state which enables the realization of an on-field head by means of a pneumatic hammer. This semifluid consistency also leads to a diameter dilatation due to the hammering, leaving no gaps among the rivet shank and the relative plate holes, differently from bolted connections. However, if involved plates are not correctly aligned, the forging operation will result in a distorted shank which presents several superficial discontinuities acting as critical stress amplifiers.

It should be remarked that current provisions for fatigue design of steel structures (EN:1993-1-9 [3]) only provide a single detail category for riveted connections ( $\Delta\sigma_c = 71$  MPa) which does not account for the actual riveted joint, although the influence of joints detailing on the cyclic behavior of steel structures is widely recognized in literature [4-16]. Moreover, the presence of the aforementioned structural imperfections is completely overlooked.

Therefore, in this paper the actual static and fatigue behavior of common types of riveted connections is parametrically investigated by means of numerical analyses.

The present work is divided in three parts. In the first section, the main features of investigated riveted connections are presented; the most relevant modeling assumptions are reported in the second part, with particular attention to damage modeling and fatigue load protocol derivation. Finally, the results of numerical analyses are discussed, highlighting the influence of the investigated parameters on both the static and cyclic response of considered riveted joints.

## 2 DESCRIPTION OF INVESTIGATED RIVETED CONNECTIONS

Four different types of lap shear riveted connections were tested in order to evaluate the influence of (i) rivet diameter, (ii) plates width and thickness and (iii) number of rivets on both static and fatigue behavior of these joints. Each adopted configuration is representative of typical details adopted in existing railway bridges.

Among the different typologies of possible constructional imperfections, in this paper only the shank distortion due to plates misalignment is considered. According to the Sustainable Bridges report [17], such kind of misalignment is considered acceptable for an existing riveted connection (i.e. connection repair or substitution is not required) if the ratio between the shank eccentricity  $e$  and the rivet diameter  $d$  does not exceed 0.15.

In order to account for possible difficulties in on-field eccentricity measuring, a maximum value of  $e/d$  equal to 0.20 was considered.

A proper nomenclature  $L-D-T-N-E$  was introduced to label each investigated joint, where:

$L$  is the considered load condition;

$D$  is the rivet diameter;

$T$  is the plate thickness;

$N$  is the number of rivets;

$E$  is the shank eccentricity.

Figure 1: Relevant geometrical parameters for the investigated rivets in presence of constructional defects.

In order to reproduce the actual technique for on-field eccentricity measuring, the parameter  $e$  has been defined as the distance between the shop head and the heat forged head of the rivet in the direction of the applied loads, as depicted in Figure 1. A total of 40 finite element analyses (FEAs) were conducted accounting for the variation of each introduced parameter (see Tab. 1).

Joint Typology	Load Conditions	Rivet Diameter D [mm]	Plate Thickness T [mm]	Number of Rivets N	Eccentricity E [e/d]
L-16-10-1-E	S (Static) or F (Fatigue Cyclic)	16	10	1	0.00 (No Imperfections) to 0.20
L-19-10-1-E		19	10	1	
L-19-12-1-E		19	12	1	
L-19-10-2-E		19	10	2	

Table 1: Main features of investigated joint configurations.

### 3 MODELLING ASSUMPTION

Finite element models (FEMs) were developed using ABAQUS 6.14 [18]. In order to reduce the computational effort, riveted connections have been modelled considering their geometrical and mechanical symmetry. Static and fatigue behavior of each connection has been investigated imposing monotonic and cyclic displacement histories at the plates tip, respectively. The adopted boundary conditions are reported in Figure 2.

All elements were discretized using solid C3D8 element type (i.e. 8-node linear brick). The mesh density was defined on the basis of preliminary sensitivity analyses; therefore, a mesh size of 1 mm was set for the connection zone, while a value of 20 mm was adopted for the plates ends, which were expected to remain in their elastic range.

Steel yielding was modelled using the Von Mises criterion. Yield stress for both rivets and plates was calibrated against experimental trials carried out by D’Aniello et al. [2]. Both kinematic and isotropic hardening were implemented by means of material parameters. Ductile damage formulation was introduced to reproduce the material degradation due to plasticization under triaxial stresses. According to Yang et al. [19], the following analytical expression for triaxiality curves was considered:

$$\varepsilon_{pl,eq,\eta} = \bar{\varepsilon}_{pl,eq} \exp(-3/2(\eta - 1/3)) \quad (1)$$

where  $\varepsilon_{pl,eq,\eta}$  is the equivalent plastic strain (PEEQ) at damage initiation for a given stress triaxiality,  $\bar{\varepsilon}_{pl,eq}$  is the equivalent plastic strain at damage initiation under uniaxial stress and  $\eta$  is the stress triaxiality, defined as the ratio between the mean pressure  $\sigma_m$  and the equivalent Von Mises stress  $\sigma_{eq,VM}$  at a given point. Adopted values of  $\bar{\varepsilon}_{pl,eq}$  were calibrated against the aforementioned experimental tests on real riveted joints. The assumed values of mechanical parameters are reported in Table 2. “Surface-to-Surface” interactions were introduced to model contact among rivets and plates.

Figure 2: Boundary condition adopted for investigated riveted joints in absence (a) and presence (b) of constructional defects.

An “Hard Contact” formulation was considered for the normal contact behavior, while a penalty formulation was used to model the tangential behavior (with friction coeff. = 0.30).

Investigated Joint	Plate Yield Stress [MPa]	Rivet Yield Stress [MPa]	Rivet Damage Strain [-]
L-16-10-1-E	298	385	0.54
L-19-10-1-E	298	461	0.53
L-19-12-1-E	298	414	0.60
L-19-10-2-E	298	350	0.32

Table 2: Adopted material parameters for the investigated riveted joints.

### 3.1 Derivation of the fatigue load protocol

In order to reproduce fatigue loads which could affect real riveted connections comparable with the investigated ones during their service life, a cyclic protocol was developed starting from the structural analysis of an existing railway riveted bridge situated in Italy (Bridge over Gesso Torrent, see Figure 3a). The investigated bridge, which is composed by three identical simply-supported spans, has a reticular structure with two main external longitudinal trusses and two supplementary internal girders supporting the overlying embankment. Longitudinal trusses are connected by means of X-shaped braces in both the transversal and horizontal direction [1]. The whole structure was modeled using SAP2000 v.21 [20] (see Figure 3b) and subjected to fatigue load trains borrowed from current Italian provisions for fatigue design of railway bridges [21]. The main features of the load models considered are reported in Table 3.

(a)

(b)

Figure 3: Overall view of riveted bridge over Gesso Torrent (a) and relative structural model made with SAP2000 (b).

“Moving Load” command was used to reproduce the effect of transient train loads, thus obtaining the variation of nodal actions through time. Among the various existing connections, the one linking the most stressed diagonal to the tension side of the truss was chosen.

The resulting loads history relative to a single rivet was finally used as load protocol for the fatigue analysis of investigated riveted connections (see Figure 4).

Load Train	Total Load [kN]	Number of Axles [-]	Train Length [m]	Daily Passages [-]
3	9400	60	385.5	7
4	5100	30	237.6	6
8	10350	46	212.5	1
9	2960	24	134.8	1

Table 3: Main features of the load trains adopted according to [21].

## 4 RESULTS OF NUMERICAL ANALYSES

### 4.1 Static behavior of investigated joints

The static behavior of each investigated joint in terms of shear strength-eccentricity and ultimate displacement-eccentricity is reported in Table 4. One can notice that the peak resistance of each investigated joint does not change significantly as the shank eccentricity  $e/d$  increases. This outcome is consistent with the failure mechanism related to all analyzed specimens (i.e. rivet shear failure for each investigated joint). Indeed, the shear resisting section of the distorted rivets is not actually influenced by the holes misalignment due to the diameter dilatation.

However, the effect of shank distortion can be appreciated in terms of both ultimate displacement and damage concentration. Due to the loss of in-plane symmetry, the material damage develops unevenly among the shear planes, as depicted in Figure 5. This leads to a reduction of joint ductility which becomes more consistent with increasing eccentricity  $e/d$ .

Moreover, this tendency is more pronounced for low values of “rivet slenderness” ratio  $t/d$ . (i.e. S-19-10-1-E specimen,  $t/d = 0.53$ ) due to the higher influence of second order bending moments caused by distorted geometry. Nevertheless, the influence of these effects on the static behavior of examined riveted joints can be considered negligible within the investigated range of defects amplitude. Indeed, as reported in Table 4, the loss of shear resistance with respect to undistorted specimens is extremely low. This outcome is in consistency with tolerances on eccentricity suggested by Sustainable Bridges Report [17].

### 4.2 Fatigue behavior of investigated joints

The fatigue behavior of each investigated joint in terms of maximum damage initiation parameter-eccentricity is reported in Table 5.

Figure 4: Cyclic protocol adopted for the fatigue analysis of the investigated riveted connections.

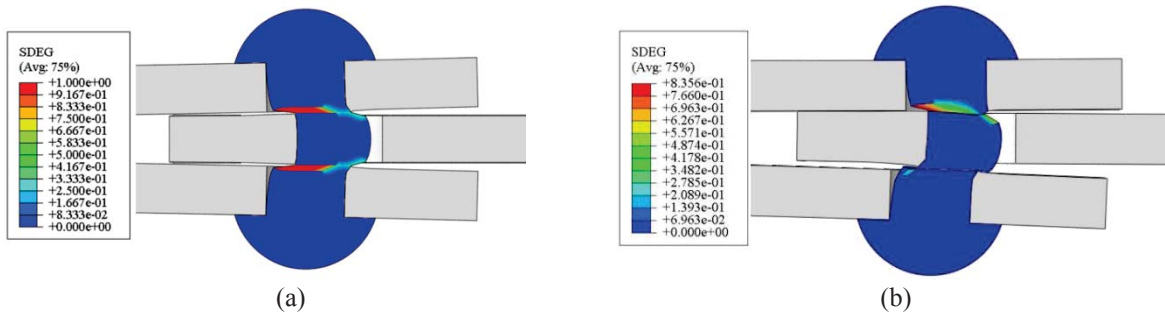

Figure 5: Distribution of scalar damage parameter at failure in absence (S-16-10-1-0.00, a) and presence (S-16-10-1-0.20, b) of imperfections.

Investigated Joint	Shear Strength [kN]					Ultimate Displacement [mm]				
	$e/d$ [%]					$e/d$ [%]				
	0	5	10	15	20	0	5	10	15	20
S-16-10-1-E	149.6	149.2	148.0	145.9	144.1	7.1	6.9	6.6	6.2	6.1
S-19-10-1-E	211.9	203.0	202.9	202.4	200.4	14.0	10.7	10.6	10.5	10.3
S-19-12-1-E	215.9	215.8	215.4	213.9	210.9	7.7	7.5	7.5	7.4	7.1
S-19-10-2-E	354.1	340.0	337.5	332.8	327.8	15.9	12.1	11.7	11.0	10.5

Table 4: Shear strength and ultimate displacement for all investigated joints in static conditions.

In all cases a sharp increase in damage parameter can be noticed for increasing values of shank eccentricity. Moreover, for higher values of  $e/d$  fracture spots relocate nearby shank discontinuities, while rivet heads are the most damaged components for undistorted specimens (see Fig. 6). In analogy with static analyses, joints with low “rivet slenderness”  $t/d$  (i.e. F-19-10-1-E specimens) are the most affected from constructional imperfections. The worst scenario is represented by F-19-10-2-E specimens in which have low  $t/d$  ratio and are further penalized by the presence of two distorted shanks, which both act as stress and damage amplifiers. Indeed, the maximum damage parameter for  $e/d = 0.20$  is 8.6 times higher with respect to undistorted joint.

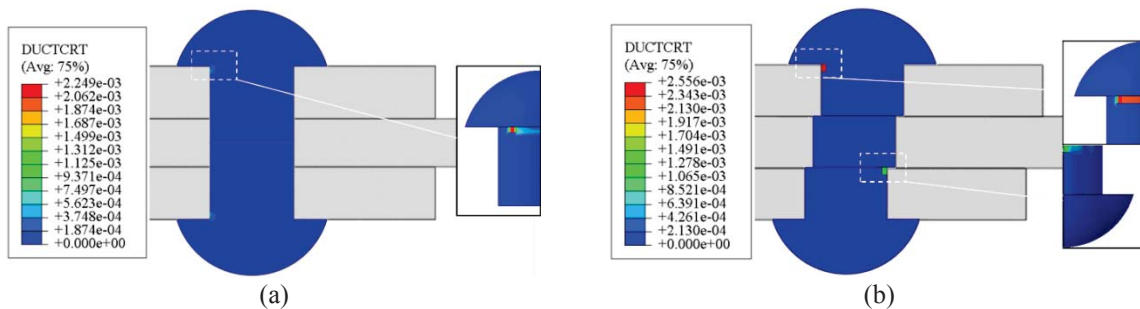

Figure 6: Distribution of damage initiation parameter after the cyclic protocol in absence (F-16-10-1-0.00, a) and presence (F-16-10-1-0.20, b) of imperfections.

Investigated Joint	Damage initiation Par. ( $\cdot 10^3$ ) [-]				
	$e/d$ [%]				
	0	5	10	15	20
F-16-10-1-E	2.25	2.38	2.47	2.51	2.56
F-19-10-1-E	0.71	1.03	1.72	2.67	2.83
F-19-12-1-E	1.17	1.63	2.04	2.10	2.12
F-19-10-2-E	0.59	1.04	3.81	4.74	5.09

Table 5: Damage initiation parameter for all investigated joints under cyclic actions.

## 5 CONCLUSIONS

The static and fatigue behavior of four different kinds of lap shear riveted joints has been studied by means of numerical analyses. The influence of constructional imperfections on the joint's response was investigated introducing hole misalignments up to 20% of rivet diameters. A proper cyclic load protocol was derived from the structural analysis of an existing riveted railway bridge situated in Italy.

From results of FEAs the following conclusions can be drawn:

- The static behavior of each investigated joint is not consistently influenced by the presence of constructional imperfections, with a maximum shear strength loss of about 5% with respect to undistorted specimens.
- However, a small difference can be noticed in terms of ultimate displacements, which decrease with increasing values of shank eccentricity; a modification of the damage mechanism is also observed due to distorted geometry.
- Ductility reduction increases for low values of “rivet slenderness”  $t/d$  due to higher second order stresses which promote damage evolution.
- The fatigue behavior of joints is highly dependent from shank eccentricity; increasing values of  $e/d$  lead to higher damages and develop of fracture spots nearby shank discontinuities.
- Similarly to the static scenario, low “rivet slenderness”  $t/d$  has a consistent influence on fatigue damage as well.
- The parametrical study will be further extended considering unsymmetrical joints, different kinds of imperfections and using standard cyclic protocols provided by EN:1993-1-9 [3].

### Abstract

*Hybrid structures are highly efficient and economical. In particular, modular solutions with tubular columns combined with horizontal light-weight girders made of cold-formed steel sections may provide a cheap and efficient system. In order to simplify the on-site erection phases, a novel plug and play joint has been proposed within the RFCS INNO3D joints project to enable industrialized and modular solutions that ensure fast-track construction and increase the quality of the finished product. The aim of this paper is the investigation of both the monotonic and cyclic behavior of this type of joint by finite element analyses. Thus, an advanced numerical model was developed and validated against experimental results performed within the INNO3D research project. The results show for a large rotational value and increase of the joint stiffness due by the contact between the joint components.*

## 1 INTRODUCTION

Nowadays increasing attention is given in the design of steel structures located seismic area to avoid brittle failure concentrating all the plastic deformation within the ductile elements [1-17]. In particular, in steel market there is a growing interest in developing new design and construction approaches that could results more efficient, safer, environmentally friendly, less labor-intensive, and can lead to buildings that are of higher standards and can be constructed in a compressed schedule [17-22]. Shortage of skilled workers, low productivity, and increasingly stringent client requirements are the incentives behind developing innovative approaches. The construction industry has been dominated by conventional construction practices which are less efficient and economical. Modular constructions provide several advantages. The economy of modular systems depends on several variables, namely: resistance to lateral load and the type of connections which plays a major role in stability and robustness of the system.

To meet the needs of clients and communities of the future it is required to rethink the design and construction processes and develop appropriate responsive strategies. A few modular construction systems are available using light-weight steel solutions, which are easily assembled in panels and delivered on site. The European project DRYCONDIS summarizes the capabilities of light-weight steel dry construction building systems [23]. Several research projects have dealt with light-weight steel systems for prefabricated steel buildings and their integration with the steel skeletal system (e.g. ETHICS; InFaSo; FrameUp; PRECASTEEL, [24-27]). However, in only a few of them, the execution phase was a main parameter considered in the development and optimization of the system.

In the light of these considerations, innovative modular constructions with hybrid systems made of lightweight steel truss girders connected to tubular columns by means of plug-and-play joints have been developed within the recent INNO3DJOINTS (acronym of “Innovative 3D joints for robust and economical hybrid tubular construction”) project in order to ensure fast-track construction and increase the quality of the finished product. This paper aims to provide a preliminary investigation of the joint under monotonic loading.

## 2 DEFENITION OF THE INNO3DJOINTS

Figure 1 (a) illustrates the main elements of the system and the details of the plug-and-play connection (b). Columns could have cold-formed rectangular, square, or circular hollow structural section, while the beams are truss girders composed of light-gauge cold-formed profiles which provides the main lateral resistance of the system. The joint is a plug and play joint which guarantee a fast and safe on-site execution. As showed in Figure 1b, the joint is connected to the column at two different levels. It is noteworthy to mention that, due to the cold-formed characteristics of the cross section, the joint is connected to the column at the end of the corner radius; these details improve the connectivity of the joint to the column, since the welding procedure of this this type of profiles could show some local imperfections. The main components are the socket and the plug: the former is made of two S-shape plates that are welded to the column's face at one end, while serves as a host for the plug on the other end. The plug is made of a T-shape and U-shape plates, and it is reinforced by stiffeners at both sides. In addition, the plug is connected to the truss on one end, and it will be locked in the socket on the other side. During fabrication of the structure in a steel workshop, the T-plug with Y-fork are assembled to the truss girder and the socket is welded to column.

The slab in this system is constructed using CLT panels, providing both the necessary gravity load-bearing capacity and enough in plane rigidity to act as a rigid plane diaphragm.

Figure 1 Structural system (a); Details of the plug-and-play connection (b)

### 3 FINITE ELEMENT MODELING OF THE JOINT

A 3D model of the test specimens was developed based on the experimental set-up as shown in Figure 2. The model was developed by means of Abaqus software [28] and all the main modelling assumptions are in line with the models developed by Tartaglia et al. [29-34]. Due to the large number of contacts, the bolts and the material nonlinearity, the full 3D model is difficult to construct and is computationally intensive. Thus, considering some simplification is necessary for the model; in this case proper boundary condition were introduced to reproduce the symmetry of the connection. A mesh transition technique is used to mesh the model. The fine mesh was used in a critical area or anywhere that the behavior of the model is important. A coarser mesh is used in areas further away from the critical zones by using a wedge element between two zones. A general contact is defined for the model. For general contact interactions, the discretization, tracking approach, and surface role assignments are selected automatically by Abaqus/Standard. A contact property that has tangential and normal behavior is assigned to the contact. The penalty method is selected for enforcing the contract. It enforces the contact by use of springs without adding a degree of freedom to the matrix structure.

Figure 2 Left: the test set-up Right: the FEM

Figure 3a shows the comparison between the numerical simulation and the experimental test in terms of force versus the displacement curve. The force is measured by the load cell while the vertical displacement is extracted from the LDTV ABS\_11 (see Figure 2). After an initial decrease, the joint shows an increase of stiffness. This additional source of stiffness is due to the contact between the T-plug and the socket.

The Von-mises stress are also depicted in Figure 3b where a large concentration of tensions can be observed at the joint location.

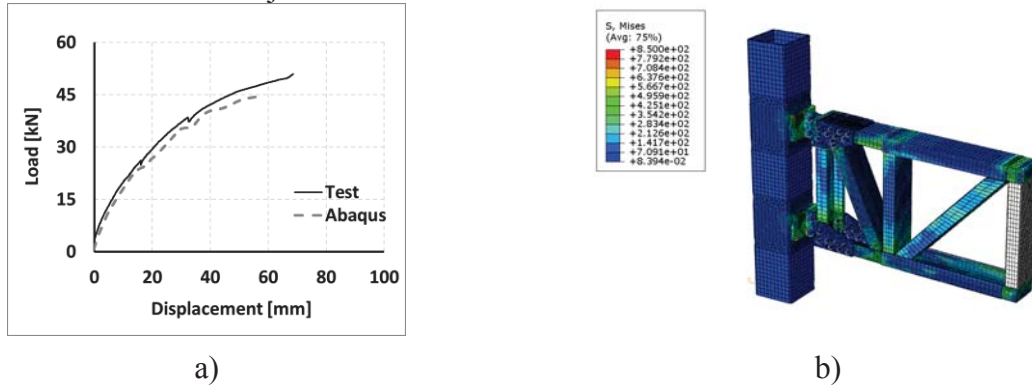

Figure 3 Force-displacement from the FEM and available experimental data.

The top joint is isolated from the system to investigate the cyclic response of the joint as shown in Figure 4a. The cyclic behavior of the joint is investigated under the ECCS loading protocol. First, a monotonically increasing displacement load (rotation) was applied to the reference point that is highlighted in yellow. From the recorded force (moment) – displacement (rotation) curve, the conventional limit of the elastic range and the corresponding displacement (rotation) were deduced based on ECCS prescriptions. The reaction forces and moments are extracted from section-1 (see Figure 2).

The cyclic behavior of the joint is evaluated and shown in Figure 4 in terms of bending moment, shear and axial force. The curves are normalized with respect to the axial, shear and bending yielding resistance evaluated from the monotonic response. The hysteretic behavior shows a fair amount of pinching which is mainly due to the opening and closing of the bolts or contact and separation of different plates in the joint.

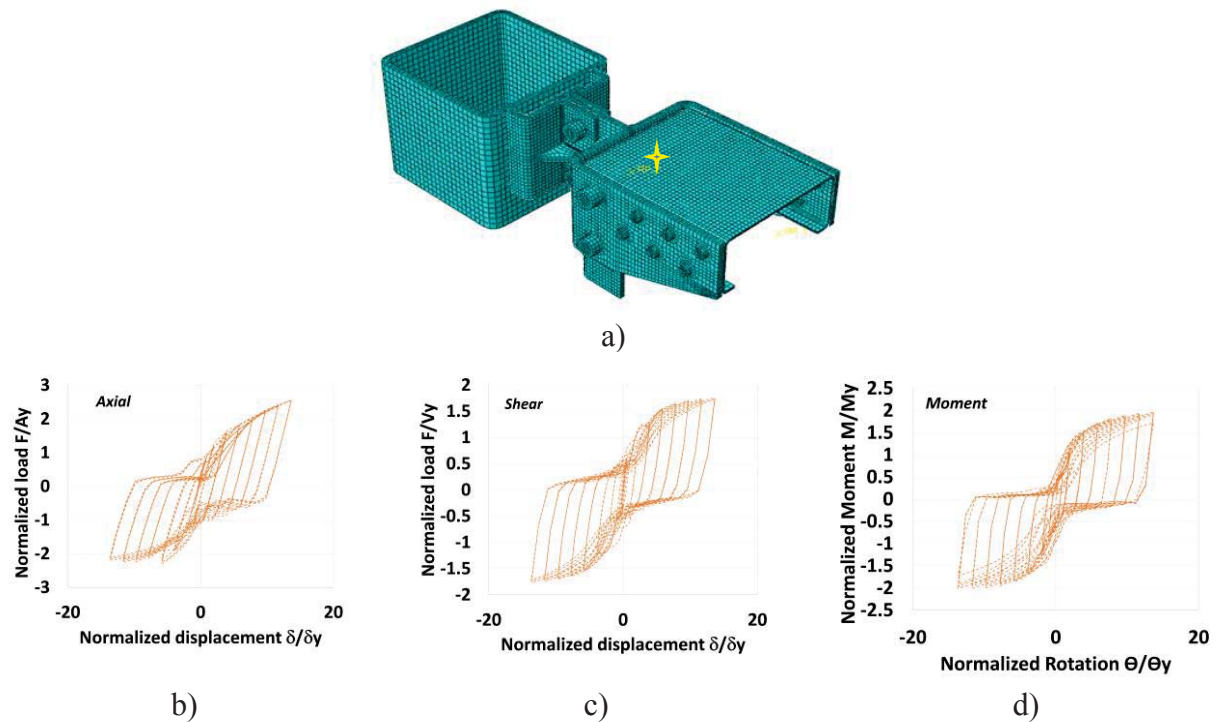

Figure 4: The cyclic behavior of the inno3Djoint

#### 4 SUMMARY AND CONCLUSIONS

INNO3DJOINTS joint is an innovative plug-and-play joint for hybrid tubular construction, whereby tubular columns are combined with cold-formed lightweight steel profiles to provide a highly efficient structural system. A finite element model of the joint was developed based and validated against the experimental test. Under monotonic loads an initial loss of stiffness due to contact between the T-plug and the socket can be observed; contrariwise for increasing value of rotation an increase of stiffness was observed. This discontinuity can be observed also when the joint is subjected to cyclic action; indeed, as observed the joint cyclic behavior is characterized by a pinching behavior.

### Abstract

*The aim of this work is to present the results of the design of Moment Resisting Frames and Dual-Concentrically Braced Frames (D-CBFs) according to the Theory of Plastic Mechanism Control. These frames are equipped with both haunched connections, analysed in the framework of the RFCS founded EqualJoints Plus research project, and FREEDAM joints analysed in the framework of the RFCS founded FREEDAM Plus. The seismic performances of the structures are investigated by both pushover and nonlinear dynamic analyses.*

**Keywords:** Prequalified connections, Concentrically Braced Frames, TPMC, Dual Systems, seismic response, FREEDAM Plus.

## 1 INTRODUCTION

The design of modern seismic resistant structures is based on a preliminary selection of the so-called dissipative zones which must be designed to assure, by means of their plastic engagement, the dissipation of the earthquake input energy. It is well known that Moment Resisting Frames (MRFs) [1]-[4] are characterized by a limited lateral stiffness and high ductility linked to the possibility of forming many plastic hinges. The location of such dissipative zones at the beam ends is commonly preferred by designing full-strength beam-to-column joints. It is recommended that beam-to-column joints are designed with sufficient over-strength with respect to the connected beams to assure their yielding accounting for the influence of random material variability and for strain-hardening occurring before the complete development of the ultimate flexural resistance of plastic hinges.

Dual Concentrically Braced Frames (D-CBFs) [6]-[7] constitute an appealing structural scheme because they combine the advantages of MRFs, which are characterized by high global ductility due to the high number of dissipative zones, and CBF, which are characterized by high lateral stiffness due to the exploitation of the axial stiffness of diagonal members. In fact, thanks to bracing members, providing additional lateral stiffness, D-CBFs allow respecting serviceability code requirements. However, they are penalized by the occurrence of buckling of bracing members in compression which governs the shape of the hysteresis loops of such dissipative zones [8]-[14]. D-CBFs are also attractive for collapse prevention requirements because they allow exploiting the local ductility supply of the MR part thus giving to the diagonal members only the stiffening task. This observation suggests a design approach where the braced frame is dimensioned to satisfy serviceability requirements while the moment resisting part is designed to satisfy ultimate limit state requirements.

It is known that, to prevent catastrophic collapses, the structural system and members should have enough strength and ductility to resist to earthquakes [15]-[23]. Therefore, a stable and reliable capacity for energy dissipation should be provided through proper design and detailing of the system, members, and joints. These latter attracted much attention because an improper design or fabrication of the connections may lead to the collapse failure of the whole structure.

In this paper, reference is made to the use of full-strength joints [24]-[30] that has been always considered the best way to dissipate the seismic input energy. In particular, the joint typology herein investigated is the so-called “haunched” connections which are characterized by a haunch at the lower flange of the beam having the aim of increasing the connection stiffness thus allowing the yielding in the beam ends. As regards code provisions, UNI EN 1993-1-8 [31] provides design rules and analytical models to predict the mechanical behavior of the joints; while UNI EN 1998-1 [32] provides additional design rules for seismic resistant joints. From the existing scientific literature, a wide data base of experimental results on beam-to-column joints is available [33]. Moreover, several research projects have been developed and devoted to investigating the beam-to-column joints behavior under both seismic and non-seismic loadings. Even though these projects have provided a large amount of data dealing with steel beam-to-column connections, none of the existing European studies has been aimed at prequalifying specific configurations for seismic areas based on parametric experimental investigations. In order to fill these gaps, the recently finished European research project EQUALJOINTS [34] was aimed at providing prequalification criteria of steel joints for the next version of UNI EN 1998-1 [32]. The following dissemination project EQUALJOINTS-PLUS [35]-[38], had the scope to promote the valorisation and dissemination of the technical knowledge and the design tools developed within the EQUALJOINTS project. The goal is to reach a wider and easier use of dissipative beam-to-column connections in steel seismic resist-

ing systems in Europe. The joint typologies selected for prequalification procedure are representative of those most adopted in European practice. In the context of the research project EQUALJOINTS [34], four types of prequalified connections are considered. In particular, three types of prequalified bolted beam-to-column joints (Figure 1 a, b and c) will be considered, as well as welded dog-bone beam-to-column joint made of heavy sections (Figure 1 d). In this paper, reference is made to “haunched” connections (Figure 1 a).

Figure 1: Beam-to-column joints investigated in the framework of EQUALJOINTS project: a) Bolted haunched joints; b) Bolted extended stiffened end-plate joint; c) Bolted extended unstiffened end-plate joint; d) Welded dog-bone joint

However, independently of the use of either full-strength or partial-strength beam-to-column joints, the main drawback of the traditional seismic resistant design strategy is intrinsic in the strategy itself. The structural damage is essential to dissipate the earthquake input energy but, on the other hand, it is the main source of direct and indirect losses. For this reason, many researchers have focused their attention on the strategy of supplementary energy dissipation with the aim to reduce the structural damage under destructive seismic events and, therefore, the direct and indirect losses. This strategy is based on the use of specific energy dissipation devices which have to be inserted between couples of points of the structural scheme for which high relative displacements or velocities are expected under the action of severe ground motions. In this work, reference is made to beam-to-column FREEDAM [39] connections that have been widely tested at the Laboratory of Materials and Structures of University of Salerno and to FREEDAM connections equipping the intersection between the diagonals of chevron brace frames (CBFs) when the structure is not a simple Moment resisting frame (MRF) but dual systems given by the combination of MRFs and CBFs.

Figure 2: Beam-to-column joints investigated in the framework of FREEDAM plus project: a) MRF FREEDAM joint; b) FREEDAM friction damper to chevron brace.

The scope of the paper is investigating the influence of both the mentioned connection typologies in the seismic response of MRFs and D-CBFs. To this scope, medium-rise structures have been designed according to the Theory of Plastic Mechanism Control (TPMC) design approach [40]-[49], which is a powerful design. The structural response was analysed by means of both non-linear static and dynamic analyses. All the activities described in this work are performed in the framework of the RFCS Project FREEDAM Plus [50] aimed at the valorisation and dissemination of the technical knowledge and the design tools developed within FREEDAM project, to reach a wider and easier use of dissipative beam-to-column connections in steel seismic resisting systems.

## 2 HAUNCHED CONNECTIONS VS FREEDAM CONNECTIONS

Bolted joints are very interesting for practice in steel buildings, owing to their inherent advantages not only in terms of high-quality execution (e.g. shop welding and bolting on site), but also highly productive erection (less time-consuming). Full strength joints are designed to guarantee the formation of all plastic deformations into the beam, which is consistent with EN 1998 strong column-weak beam capacity design rules (i.e. non-dissipative joint).

“Haunched” connections [51] increasing the web depth also makes an increase of the height of panel zone, which reduces the panel zone yielding. In that case a greater beam plastic rotation is needed to achieve an equivalent seismic energy dissipation. Application of the haunches assures that plastic hinges form in the beams which increases the global seismic performance of steel moment resisting frames. Appropriate detailing and use of “haunched” joints could be an effective way for ductile design of steel frames. The haunched connection used in this paper is described in Figure 3 where  $M_{j,Rd}^n$  is the joint resistance,  $M_{pl,b,cf,Rd}^e$  is the beam resistance. All the prequalifying requirements reported in Figure 3 are finalized to the stiffening of the panel zone whose strength is also calibrated not to yield in case of destructive seismic events.

					
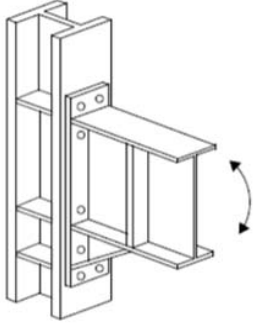

Joint Type	Geometry	Strength		Stiffness	
		Connection:	Panel Zone:	Connection:	Panel Zone:
<b>EH-S:</b> Full-strength with strong panel zone	$\frac{h_h}{h_b} = 0.45$  $\frac{s_h}{h_b} = 0.65$ $z_{wp} = h_b + h_h$	$\frac{M_{j,Rd}^n}{M_{pl,b,cf,Rd}^e} = 1.3$	External nodes: $\frac{V_{wp,Rd}^n \cdot z_{wp}}{M_{pl,b,cf,Rd}^e} = 1.65$	$\frac{s_{con,ini}}{s_b} = 80$	External nodes: $\frac{s_{wp,ini}}{s_h} = 55$
			Internal nodes: $\frac{V_{wp,Rd}^n \cdot z_{wp}}{2 \cdot M_{pl,b,cf,Rd}^e} = 1.65$		Internal nodes: $\frac{s_{wp,ini}}{2 \cdot s_h} = 55$

Figure 3: Details of “Haunched” connections

FREEDAM connections, studied in the framework of the recently accomplished homonymous project (RFSR-CT-2015-00022) have a wide-ranging use because it is a technology that

can be used both in the construction of new buildings and for the seismic rehabilitation of existing buildings. From the technological point of view, the innovation regards the conception of beam-to-column connections. In fact, beam-to-column connections are equipped with friction dampers which can be located either at the bottom flange level or at the levels of both the flanges. Such friction dampers must be designed to assure the transmission of the beam bending moment required to fulfil serviceability limit state requirements and to withstand without slippage the gravity loads. In addition, they must be designed to assure the dissipation of the earthquake input energy, corresponding to the collapse prevention limit state, without any damage. FREEDAM joints are extremely robust, because they are characterized by a first phase of the response corresponding to the damper slippage and by a second phase in which a secondary resisting mechanism is activated with the bolts acting in shear and the plate elements subjected to bearing. The added value to what has already been achieved at both European and worldwide level is the increase the safety buildings and reduction of the direct and indirect costs related to the development of structural damage in case of rare seismic events or exceptional loads. The friction resistance is calibrated by acting on the number and diameter of bolts and their tightening torque governing the preloading. The flexural resistance results from the product between the damper friction resistance and the lever arm. Such connections exhibit wide and stable hysteresis loops without any damage to the connection steel plate elements, so that they can be referred as “Free from Damage Connections”.

FREEDAM joints can be designed according to the following equation:

$$M_{f.Ed} \leq M_{f.Rd} = \frac{\mu_{st} n_b n_s P_f}{\gamma_{F2}} h_f \quad (1)$$

where  $\mu_{st}$  is the average value of the static friction coefficient equal to 0.76,  $n_b$  is the number of bolts,  $n_s$  is the number of the contact surfaces equal to 2,  $h_f$  is the lever arm given as the sum of  $H$  (Figure 14) and  $h_b$  (height of the beam),  $\gamma_{F2}$  is the partial safety factor accounting for the randomness of friction and bolt preload, and it is equal to 1.26,  $P_f$  is the preloading force that has to be calibrated to assure that the FREEDAM connection resistance is as much close as possible to the design moment  $M_{f.Ed}$  at the column face resulting from the seismic load combination. Therefore:

$$P_f \cong \frac{M_{f.Ed} \gamma_{F2}}{\mu_{st} n_b n_s h_f} \quad (2)$$

The bolt preloading should be between 40% and 100% of the maximum bolt preloading allowed by code provisions (EN 1993-1-8).

The number of bolts changes according to the standardised devices (Table 1). The friction damper to be adopted must be selected in function of the beam height  $h_b$  and of the increase of the lever arm due to the haunch resulting from the damper geometry (Figure 4).

Device	Number of bolts $n_b$
D1	4
D2	4
D3	6
D4	8
D5	8

Table 1: Number of bolts of the prequalified devices

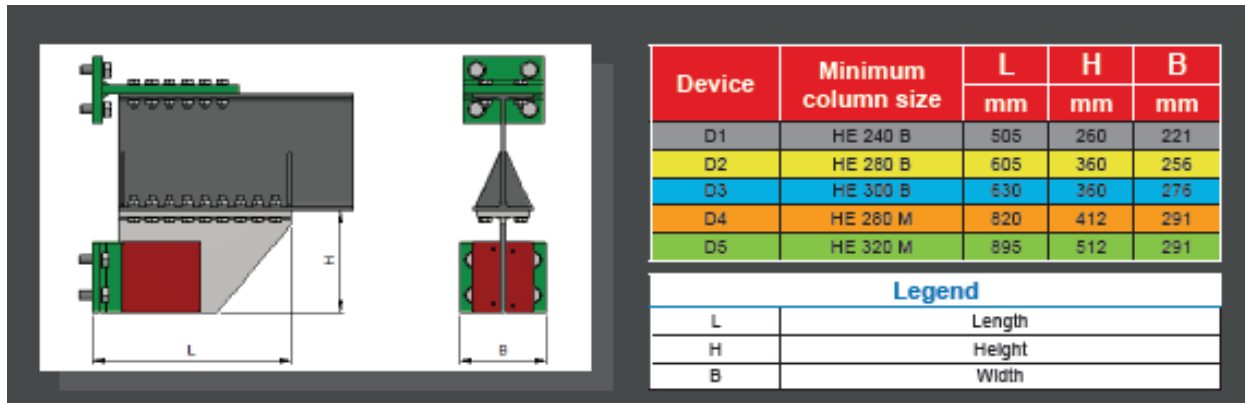

Figure 4: Dimension of prequalified FREEDAM connections

It is important underlining the need to perform a local hierarchy criterion to prevent the beam yielding that can be expressed as follows:

$$M_{b,Rd} \geq \gamma_{rm} M_{f,Rd} \left( \frac{l-L}{l} \right)$$

where  $\gamma_{rm} = 1.60$  [52],  $M_{b,Rd}$  is the beam plastic moment,  $M_{f,Rd}$  is the FREEDAM joint resistance (Eq. (1)),  $l$  is the beam length and  $L$  is the device dimension as reported in Figure 4.

### 3 DESIGN APPROACH

The design approaches herein proposed regard the Theory of Plastic Mechanism Control [40], [53]-[56]. The Theory of Plastic Mechanism Control is a design approach based on a rigorous theoretical background. It assures the development at collapse of a mechanism of global type. TPMC exploits the kinematic theorem of plastic collapse extended to the concept of mechanism equilibrium curve:

$$\alpha = \alpha_0 - \gamma \delta \quad (3)$$

where, following the theory of rigid-plastic analysis,  $\alpha_0$  is the first order collapse multiplier of horizontal forces,  $\gamma$  is the slope of the linearized mechanism equilibrium curve due to second order effects and  $\delta$  is the plastic top sway displacement. It means that in the case of the global mechanism Eq. (3) becomes:

$$\alpha^{(g)} = \alpha_0^{(g)} - \gamma^{(g)} \delta \quad (4)$$

while in the case of undesired mechanism becomes:

$$\alpha_{i_m}^{(t)} = \alpha_{0.i_m}^{(t)} - \gamma_{i_m}^{(t)} \delta \quad (5)$$

where  $\alpha_0^{(g)}$  and  $\alpha_{0.i_m}^{(t)}$  are the first order collapse mechanism multipliers for global and undesired mechanism, respectively;  $\alpha^{(g)}$  and  $\alpha_{i_m}^{(t)}$  are the collapse multiplier of horizontal force for the global and undesired mechanism, respectively and  $\gamma^{(g)}$  and  $\gamma_{i_m}^{(t)}$  are the slope of mechanism equilibrium curve for the global and undesired mechanism, respectively. TPMC states that the mechanism equilibrium curve corresponding to the global mechanism (Eq. (4)) has to be located below those corresponding to all the undesired mechanisms (Eq. (5)) until a design displacement  $\delta_u$  compatible with the local ductility supply (Figure 5). The column sections at each storey that guarantee a global collapse mechanism are the unknowns of the design problem, while the dissipative zones are preliminarily designed according to the first principle of capacity design. In this paper, the ultimate design displacement  $\delta_u$  is computed as:

$$\delta_u = \theta h_{ns} \quad (6)$$

where  $\theta$  is the target rotation of the plastic hinge that is assumed equal to 0.04 rad neglecting the higher stiffness of braces, and  $h_{ns}$  is the building height. The plastic hinge rotation is set equal to the interstorey drift ratio, since the idealized behavior of the structure is rigid-plastic. It is worth noting that P-Delta second order effects are taken into account using the TPMC design approach and, as a consequence, does not deeply affect the design as the use of the  $\theta$  [57] factor proposed in the framework of Eurocode 8 [32], thus allowing to optimize the design overstrength of the structure and the non-linear response as well.

Figure 5: TPMC statement.

#### 4 STUDY CASE

The seismic resistant structural system is a perimeter seismic resistant system. The inner bays are pinned and designed for gravity loads only. The building has 4 storeys and 4 bays. The bay span is equal to 6.00 m; the interstorey height is equal to 3.50 m. Stairs are located outside the analysed building by means of an independent structure as the same as the elevator. The seismic resistant scheme of the building is depicted in Figure 6 for X direction. The elevation configuration is reported in Figure 7. The material adopted for the structure is steel grade S355 using a partial safety factor equal to 1, so the nominal yield stress is 355 MPa for beams and for columns. The following permanent loads are considered:

- Permanent loads on floors and roof:  $3,25 + 0,75 = 4,0 \text{ kN/m}^2$
- Permanent loads of external walls:  $1,0 \text{ kN/m}^2$

while the live loads are equal to  $3.50 \text{ kN/m}^2$  for current floors and  $3.00 \text{ kN/m}^2$  for the roof.

The design horizontal forces have been determined according to the new Eurocode 8 draft [58] spectra assuming a reference spectral acceleration at plateau of  $8.5 \text{ m/s}^2$ , a behaviour factor equal to 6.5 for MRFs and D-CBFs with FREEDAM joints and 4.8 for D-CBFs with traditional haunched connections.

Serviceability requirements have been checked by response spectrum analysis to compute the elastic displacements and to derive the interstorey drift values to be compared with the corresponding limits according to:

$$d_r = 0.020 h \quad (7)$$

where  $d_r$  is the relative displacement increased by the behaviour factor and  $h$  is the interstorey height. The limitation is the one reported into the new Eurocode 8 draft [59].

Figure 8 shows the comparison in terms of weight among MRFs and D-CBFs equipped with haunched and FREEDAM connections. It is evident that in both cases the structures with traditional connections leads to heavier structures.

Figure 8: Comparison in terms of weight among MRFs and D-CBFs equipped with haunched and FREEDAM connections designed according to TPMC.

## 6 MODELING ASSUMPTIONS

The modelling of these structures is carried out in SAP 2000 ambience [60] according to the scheme reported in Figure 7. The leaning column (Figure 7) is used to consider the vertical loads acting on the frame (including masses) and the second order effects. The material steel grade is S355 where the coefficients 1.20 and 1.10 are the overstrength factor due to random material variability according to the Probabilistic TPMC [49] and the strain hardening, respectively. [61]-[66]. The plastic behaviour of members has been modelled in terms of lumped plasticity by P-hinge properties.

### 6.1 Structures with traditional joints

Beams and columns have been modelled by means of beam-column elements, whose non linearities have been concentrated in plastic hinges (“Moment M3” elements). On the beams, hinges are at the end of haunched connection, namely at a distance  $s_h$ , from the face of the column; while on the columns they are assigned with a relative distance of 0 and 1. Of fundamental importance are the demand for plastic rotation during the development of the kinematic mechanism and the capacity for plastic rotation. In the case of columns with dimensionless normal stress lower than 0.30 and beams in flexure, the plastic deformation capacity is expressed as a multiple of the chord rotation at yielding  $\vartheta$ , defined as a property of the member itself.

In particular, for columns arranged strong axis and for beams, the rotation of the member is:

$$\theta_y = \frac{\gamma_{rm} M_{pl,y} l_m}{6EI_m} \quad (8)$$

For columns arranged weak axis, the rotation of the member is:

$$\theta_z = \frac{\gamma_{rm} M_{pl,z} l_m}{6EI_m} \quad (9)$$

where  $M_{pl,y}$  and  $M_{pl,z}$  are the plastic moment of the member for y and z axis respectively;  $l_m$  is the length of the member;  $I_m$  is the moment of inertia; E is the elastic modulus and  $\gamma_{rm}$  is the material overstrength coefficient place equal to 1.25. Plastic rotation capacity at the end of

beams or columns with dimensionless axial load  $v$  not greater than 0.30 in Table B.1 of EC8-3 [67] are reported, as shown in Figure 6. The hysteresis type is kinematic.

Point	Moment/SF	Rotation/SF
E-	-0.67	$0.075/v$
D-	-1.2	$0.028/v$
C-	-1.2	$0.016/v$
B-	-1	0
A	0	0
B	1	0
C	1.2	$0.016/v$
D	1.2	$0.028/v$
E	0.67	$0.075/v$

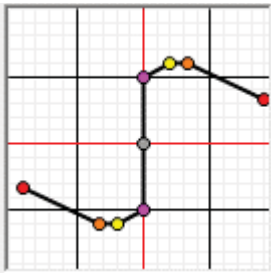

Table 6: Beams and columns hinge model.

To model the plastic hinge of the bracing diagonals in Sap2000 we start from the Georgescu model [68] generally used for cyclic analysis (Figure 9) [67].

Figure 9: Georgescu model for cyclic analysis

The model used for the pushover analyzes starts from a first simplification of the Georgescu model (Figure 10) that exploits the OA, AB and BC traits for compression. On the other hand, in traction the behavior is defined with a Perfectly Plastic Elastic bound (EPP).

Figure 10: First simplification of the Georgescu model for pushover analysis

The equations of model branches are reported in the following:

- Initial imperfection

$$f_0 = \frac{W}{A} \alpha (\bar{\lambda}^2 - 0.04) \quad \text{with } \alpha = 0.21, \bar{\lambda} = \frac{\lambda}{\lambda_y} \quad (10)$$

- OA branch:

$$P = \frac{EA}{L} \delta_{OA} = K_d \delta_{OA} \quad \text{with } P \text{ limited to } P_{crit}; \quad \delta_A = \frac{P_{crit}}{K_d} \quad (11)$$

- AB branch:

$$f_{tB} = \frac{M_{pl}}{P_{crit}} \left( 1 - \frac{P_{crit}}{P_y} \right) \quad (12)$$

$$\delta_B = -\frac{P_{crit}L}{EA} + \frac{\pi^2}{4L} (f_{tB}^2 - f_0^2) \quad (13)$$

- BC branch:

$$f_t = \frac{M_{pl}}{P} \left( 1 - \frac{P}{P_y} \right) \quad \text{with } P \text{ generic } < P_{crit} \quad (14)$$

$$f_0 = \delta_{BC} = -\frac{PL}{EA} + \frac{\pi^2}{4L} (f_t^2 - f_0^2) \quad (15)$$

- OF branch:

$$P = \frac{EA}{L} \delta_{OF} = K_d \delta_{OF} \quad \text{with } P \text{ limited to } P_y; \quad \delta_F = \frac{P_y}{K_d} \quad (16)$$

- FG branch:

$$P = P_y \quad \forall \delta_{FG} \quad (17)$$

A second simplification adopted in the Sap2000 model consist in considering the OA and OF sections as rigid, while the BC section is represented with bilinear approximation (Figure 11). The elastic behaviour is demanded to the beam-column element representing the diagonal section.

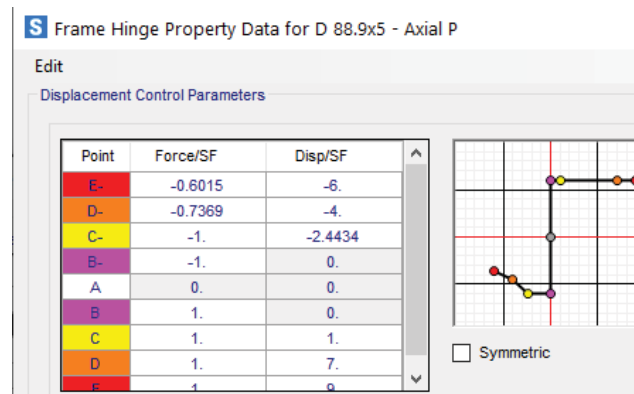

Figure 11: Second simplification of the Georgescu model for pushover analysis, in Sap2000

The bilinear approximation of the BC section was obtained by considering two points of the curve, or those corresponding to the limit displacements provided by Eurocode for the compressed diagonals. These points were also identified in traction (on the horizontal branch) according to the limits given for taut diagonals.

For braces in compression the inelastic deformation capacity should be expressed in terms of the axial deformation of the brace, as a multiple of the axial deformation of the brace at buckling load,  $\Delta_c$ . For braces in compression (except for braces of eccentric braced frames) the inelastic deformation capacities at the three LSs may be taken in accordance with Table B.2 of EC8-3 [67]. For braces in tension the inelastic deformation capacity should be expressed in terms of the axial deformation of the brace, as a multiple of the axial deformation of the brace at tensile yielding load,  $\Delta_t$ . For braces in tension (except for braces of eccentric braced frames) with cross section class 1 or 2, the inelastic deformation capacities at the three LSs may be taken in accordance with Table B.3 in EC8-3 [67]. To allow the diagonal buckling and therefore, their cyclic behaviour the diagonal must be split into two parts and the middle node must be put out of plane with an initial imperfection.

## 6.2 Structures with FREEDAM joints

In the structures with FREEDAM connections the beams and columns have the same plastic hinge described above. The P-hinge properties representing the FREEDAM connections are rigid perfectly plastic, and they are located at the column face, i.e. where it is expected the device rotation. The rotation depends on the level arm of the device used. Under the bending action, the node is forced to rotate around the center of rotation, located at the base of the upper T-stub, and the dissipated energy is guaranteed by the alternating sliding of the bolts on the vertical stainless-steel plate (Figure 12).

Figure 12: Center of rotation of FREEDAM hinge

In particular, the FREEDAM rotation is:

$$\vartheta_y = \frac{d}{H} \quad \text{with } H = h_b + b \quad (18)$$

where  $d$  is the distance between the bolt and the slot,  $h_b$  is the beam height,  $b$  is the distance between the center of gravity of the bolts and the lower flange of the beam.

As already mentioned, the bracing diagonals of the D-CBFs structures equipped with FREEDAM dampers do not suffer any damage in the case of a seismic event as the energy dissipation occurs through the friction dampers placed at the chevron braces intersection.

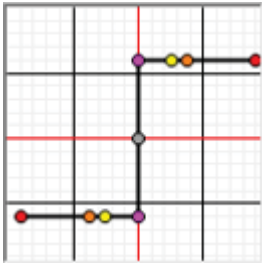

Point	Moment/SF	Rotation/SF

C	1	0.04	
D	1	0.06	
E	1	$\vartheta_y$	

Table 7: FREEDAM hinges model.

For the sole purpose of carrying out pushover and non-linear dynamic analyses, this friction device was modeled as a “short link” with a cross-section equal to the diagonals it joins and a cross section axial area of zero. The length of the link is:  $l_{link} = h_b/2 + 260$ ; in other words, it has been set equal to half the height of the beam plus the height of device D1.

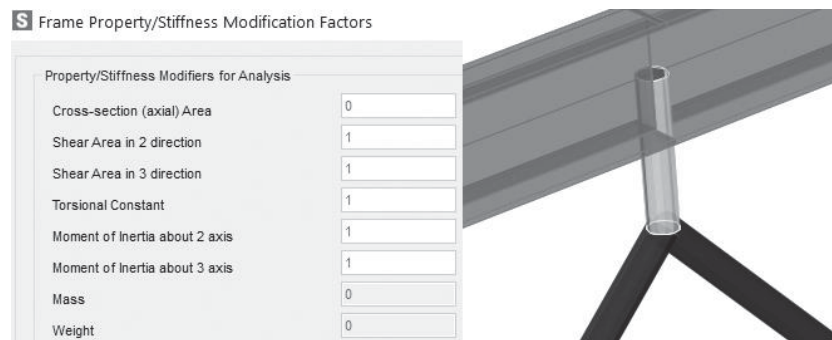

Figure 13 – Friction dampers model for pushover and non-linear dynamic analyses

A rigid plastic frame hinge “Shear V2” behaviour is assigned to “link” members with a max displacement equal to:  $d_{max} = 0.04 \cdot h_i = 0.04 \cdot 3.50 = 0.14$  m; where  $h_i$  is the inter-storey height of the structure. In the definition of FREEDAM hinges, the bending and shear strength of the beam-column and diagonal intersection devices was amplified with the coefficient  $\gamma_{rm}$  equal to 1.6 [52].

D	1	0.07	
E	1	$d_{max}$	

Table 8: – FREEDAM hinges “Shear V2” model

## 7 PUSHOVER ANALYSES

Pushover analyses are led in displacement control considering both geometrical and mechanical nonlinearities under two lateral load patterns, as suggested by EC8: a load distribution corresponding to the fundamental mode shape and a uniform distribution proportional to seismic masses at each floor. The response parameters monitored by the performed pushover analyses are illustrated in Figure 14. Pushover analyses are carried out on SAP2000 computer program.

In particular,  $V_u$  is the base shear at maximum plastic capacity of the structure,  $V_1$  is the base shear at first plastic event;  $\delta_1$  and  $\delta_{max}$  are the roof displacements corresponding to the formation of the first plastic hinge and to the first occurrence of the structural collapse corresponding to the achievement of the ultimate rotation.

Figure 14: Monitored parameters in capacity curves.

Among the strength parameters monitored the base shear  $V_u$  is a measure of the overall overstrength of the structure. In addition, the ratio  $V_u/V_1$  is a measure of redundancy. This value depends on the frame configuration, formation of the collapse mechanism, redistribution capacity and gravity loading. Conversely,  $V_1$  can be considered as an overdesign factor related to aspects of the design procedure such as differences between actual and nominal material strength, member oversizing due to choices of commercial cross section and design governed by deformation and/or non-seismic loading. The  $\mu$  factor is defined as:

$$\mu = \frac{\delta_{max}}{\delta_1} \quad (19)$$

where  $\delta_{max}$  is the roof displacement at structural collapse and  $\delta_1$  is the roof displacement associated to formation of the first plastic hinge. From the comparison of pushover response curves (from Figure 15 to Figure 18) it is observed that the D-CBF designed according to EC8 are characterized by larger overstrength than the corresponding structures designed according to TPMC. Moreover, EC8 rules induce overdesigning the braces to satisfy both slenderness limits and the variation of brace overstrength along the building height, while TPMC do not have such requirements. In general, the differences among the different “haunched” connections are negligible.

Figure 15: Push-over curves for 4 Storey MRFs with traditional connections

Figure 16: Push-over curves for 4 Storey D-CBFs with traditional connections

Figure 17: Push-over curves for 4 Storey MRFs with FREEDAM connections

Figure 18: Push-over curves for 4 Storey D-CBFs with FREEDAM connections

In Figure 19 and Figure 21 the redundancy and the ductility of the structures are reported, respectively. It is observed that the highest values of redundancy and ductility are exhibited by the structures designed by EC8. The presence of the “haunched” connections seems to affect not too much the seismic performances of the structures while the effect of balanced panel zone is easy pointed out because of higher values of the ductility.

About global ductility (Figure 19-Figure 20), it can be noted that the MRFs\_FREEDAM and D-CBFs\_FREEDAM structures have a higher ductility if compared with structures equipped with traditional joints.

Figure 19: Ductility for MRFs with traditional and FREEDAM connections

Figure 20: Ductility for D-CBFs with traditional and FREEDAM connections

About the system overstrength (Figure 21-Figure 22), it can be observed that in traditional structures it is higher than the FREEDAM ones. However, this redundancy is higher than the one suggested by the new Eurocode draft [59].

Figure 21: Redundancy for MRFs with traditional and FREEDAM connections

Figure 22: Redundancy for D-CBFs with traditional and FREEDAM connections

## 8 DYNAMIC NON-LINEAR ANALYSES

Non-linear Dynamic Analyses [69] are also performed to investigate the structural performance for the 3 limit states defined in EN1998-3 [67], namely damage limitation (DL), significant damage (SD) and collapse prevention (CP). EN1998-3 [67] associates a seismic intensity with each limit states and establishes performance limits related to global and local damage. The IDA analyses have been carried out for three increasing values of PGA value corresponding to the following limit state Damage limitation (DL), Severe Damage (SD) and Near Collapse (NC). The values of the multiplier of accelerograms are assumed equal to 0.59, 1 and 1.73 for DL, SD and NC [67], respectively. The non-linear dynamic analyses are carried out using the same structural model adopted for pushover analyses. Rayleigh formulation for a 5% damping has been assumed with the proportional factors computed with reference to the first and second mode of vibration. In addition, first  $T_1$  and second  $T_2$  periods of vibration are required and reported in Table 10. Record-to-record variability has been accounted for by considering 10 recorded accelerograms selected from ESM [70]. In Table 9 the analyzed records (Earthquake name, Date, Duration, Station name, Station Country, moment magnitude (MW), local magnitude (ML) and Fault mechanism) have been reported.

Station Code	Station Name	Earthquake name	Date	Network	Mw
BAR	Bar-Skupstina	NW_Balkan_Peninsula	15.04.1979	EU	6.9
CSO1	CARSOLI1	L'Aquila	06.04.2009	IT	6.1

MZ102	Accumoli	Central_Italy	30.10.2016	3A	6.5

Table 9: Analyzed ground motion records

These recorded accelerograms have been selected to approximately match the code elastic response spectrum [58]. In other words, the spectra of the 7 recorded accelerograms have been properly scaled to let their average value to be compatible with the design EC8 spectrum. The accelerogram multipliers are reported in the Table 11.

Scheme	TPMC	
	$T_1$ (s)	$T_2$ (s)
MRFs TRADITIONAL	1.62	0.48
MRFs FREEDAM	1.63	0.52
MRFs TRADITIONAL	0.84	0.27
MRFs FREEDAM	0.77	0.27

Table 10: First and second vibration periods

Station Code	Length (s)	Step recording (s)	Scale Factor (-)
BAR	47.83	0.01	1.11
CSO1	99.80	0.01	11.7
KAL1	30.02	0.01	1.3
MCT	96.38	0.01	5.85
MZ12	82.67	0.01	3.64
MZ102	77.15	0.01	1.04
PZI1	63.45	0.01	9.75

Table 11: Accelerogram multipliers, length and step recording

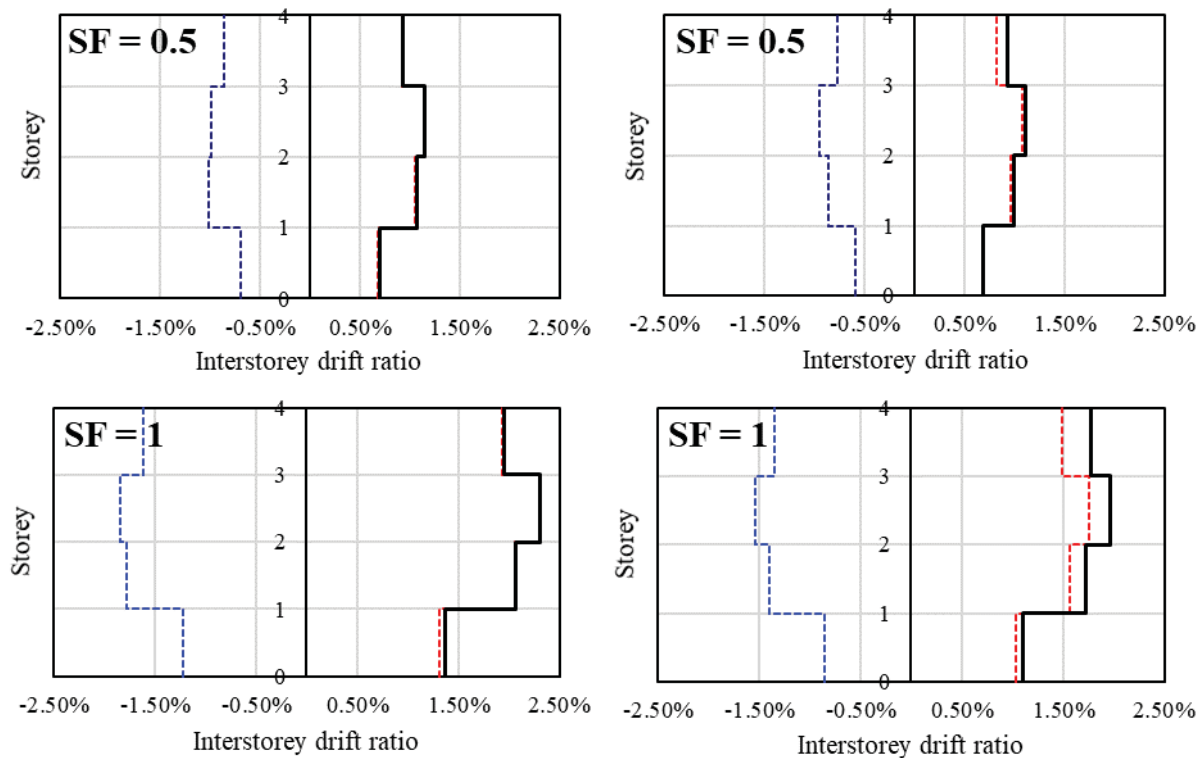

Figure 23: Comparison between natural signals average spectrum and EC8 design spectrum

From dynamic analyses it can be observed that the soft-storey mechanism does not develop, but the collapse mechanism is almost global, i.e. it develops a pattern of hinge compatible with the global mechanism.

From a comparison between the seismic performance of the structures with traditional connections and the same structures equipped with FREEDAM connections given in terms of Maximum Interstorey Drift, it is possible to observe that the structure equipped with FREEDAM connections at beam-to-column joint show, on average, better performances if compared with full strength joint ones. It is due to the high dissipative capacity of FREEDAM connections which do not present relevant degradation under cyclic loading. In addition, it is important observing that the performances of the structures equipped with FREEDAM connections can be higher if the involvement of bolt in shear is considered after the achievement of the ultimate stroke of dampers. However, the maximum stroke is never achieved even at Near Collapse limit state. The average maximum absolute peak interstorey drift of FREEDAM structures is lower than the structures with traditional full-strength joints for MRFs. In particular this happens for increasing values of PGA corresponding to the multipliers 1 and 1.5. Conversely, for the D-CBFs structures the opposite occurs, this is probably due to the insertion of the friction device at the top of chevron braces which guarantees a maximum displacement that can be reached of 14 cm. In Figure 24 and Figure 25 the comparison between MRFs and D-CBFs in terms of peak interstorey drift for each limit state is reported.

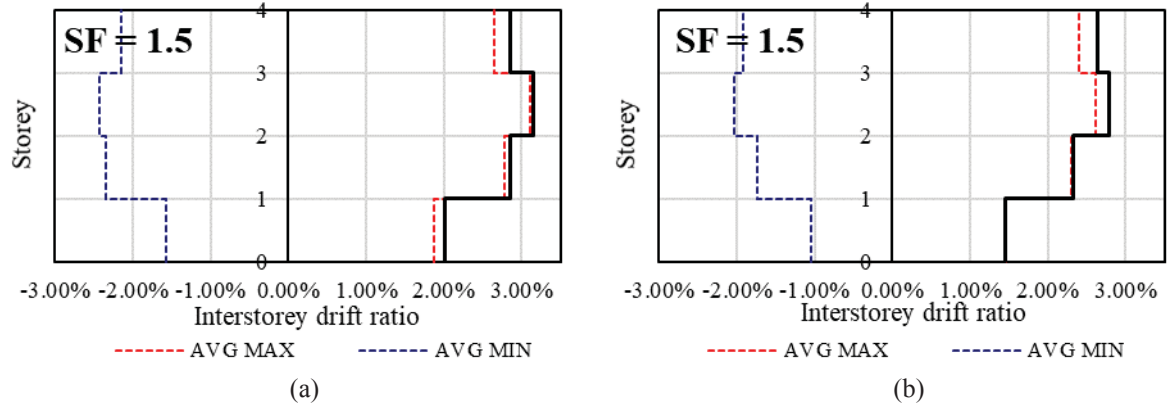

Figure 24: Peak interstorey drift curves for MRFs equipped with both traditional haunched connections and FREEDAM connections

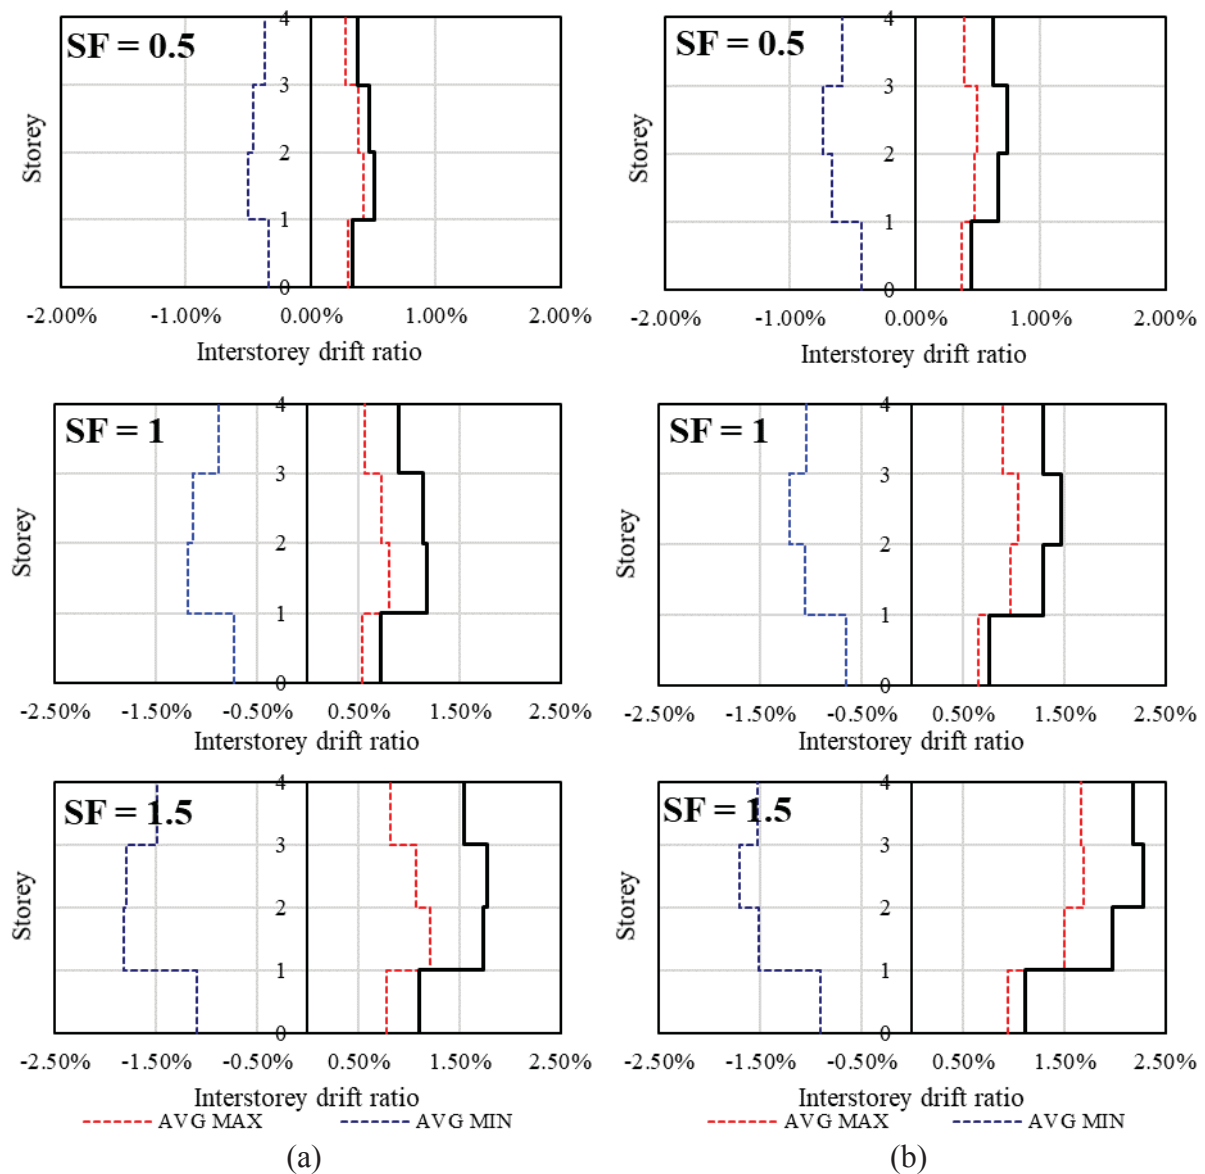

Figure 25: Peak interstorey drift curves for D-CBFs equipped with both traditional haunched connections (a) and FREEDAM connections (b)

## 9 ACKNOWLEDGEMENTS

The research leading to the results presented in this paper has received funding from the European Union's Research Fund for Coal and Steel (RFCS) research program under grant agreement n° RFCS-AM-2019-899321. The support of the European Commission within RFCS Research & Innovation is gratefully acknowledged.

## 10 CONCLUSIONS

- The work herein presented, developed in the contest of the RFCS Project FREEDAM Plus.
- Both Dual CBFs and MRFs low rise structures are designed considering traditional connections and FREEDAM connections.
- The design methodology adopted is the Theory of Plastic Mechanism Control (TPMC).
- The comparison in terms of weight among MRFs and D-CBFs equipped with haunched and FREEDAM connections shows that in both cases the use of traditional connections leads to heavier structures.
- From the pushover it is observed that the redundancy is higher for the structure with traditional connections
- Conversely, the ductility is higher for the structures equipped with FREEDAM connections.
- From the Dynamic Analysis point of view it is possible to observe that structures equipped with FREEDAM connections have better seismic performance than structures equipped with traditional connections.
- The TPMC has proved to be an excellent design tool for both traditional and FREEDAM structures assuring that columns sections are not involved in plastic range.

### Abstract

*The recent use of the 3D Laser Cutting Technology in the field of civil engineering has led to the development of novel typologies of steel beam-to-column connections made by welding circular hollow section columns (CHS) to through-all members. The main feature of these joints is that they are able to provide higher flexural strength, stiffness and energy dissipation capacity compared to the corresponding joints with elements simply welded to the external surface of the hollow section. Currently, there are no codified rules for such a type of structural details and, consequently, the design of these joints implies the development of complex FE models. Aiming at filling the knowledge gap regarding the structural flexural behaviour of CHS through I-beam joints, a research activity is currently ongoing at the STRENGTH laboratory of the University of Salerno with the objective to provide simple analytical tools for the design and modelling of such connections through the component method, both under monotonic and cyclic loading conditions.*

*This paper deals with the preliminary study of the behaviour of one of the elementary components characterising the response of beam-to-column joints composed by CHS columns and I-beams, which is the "plate transversally welded to the column in tension/compression". This component is meant to model the local behaviour exhibited by the CHS tube at the upper/lower beam flange level. This component is very important because it governs the deformability of the connection and may limit the resistance of the joint due to the local failure of the CHS tube. In the performed work, monotonic and cyclic tests on specimens representative of realistic geometric configurations of beam-to-column joints have been carried out. Subsequently, a finite element (FE) model, representative of the analysed connection, has been developed and validated against the experimental results.*

**Keywords:** component method, laser cutting technology (LCT), experimental activity, FEM.

## 1 INTRODUCTION

In the last decades, the 3D-Laser Cutting Technology (3D-LCT) has proved to be very useful in many applicative fields since it allows to manufacture a mass production with high accuracy. The only exception regards the field of civil engineering because of the relevant cost of large-scale structural components. Nevertheless, the 3D-LCT is a good solution when very complex geometrical components have to be manufactured; an example of such a case is represented by steel beam-to-column connections between circular hollow section (CHS) columns and double-tee beams. In fact, until now, except for the study of the behaviour of tubular profiles ([1]-[4]), some different solutions for coupling the aforementioned profiles have been conceived: i) the beam is simply welded to the external surface of the column [5]; ii) plates, welded to the flanges of the double-tee profile, intersect the column [6]; iii) the beam is welded to collar plates externally welded or bolted to the column [7]; iv) the connection is filled with concrete, while the beam is welded to the external surface of the column [8]. The first solution is very easy to manufacture, but the obtained connection provides low stiffness and resistance such that it can be adopted only in the case of pinned or semi-continuous frames [9]. The second and the third solution, instead, are good alternatives but the need of conceiving complex special elements [10] represents a relevant drawback. The fourth approach, instead, induces the slowdown of the construction process due to the pouring of concrete on-site [11].

The briefly above summarised existing solutions well clarify the possibilities offered by the beam-to-column connection between CHS columns and through-all beams obtained by adopting the 3D-LCT. In fact, the cut of the tubular profile according to the shape of the double-tee section guarantees the beam to cross the CHS before welding both the members, increasing, in such a way, both the stiffness and the resistance of the joint without appealing to additional plates or concrete. Because of these benefits, a relevant interest in the technological aspects [10] and mechanical behaviour exhibited by the aforementioned beam-to-column connection recently arose. In particular, at the University of Salerno, experimental, numerical and theoretical activities have been carried out in order to study the resistance and the stiffness of the analysed joint. As results of the first step of the study, formulations to predict the flexural strength and initial stiffness of CHS columns to through-all I-beam connections have been proposed ([12]-[14]). These equations have been analytically derived starting from the behaviour of the easiest components in which the connection could be simplistically divided: the hollow section subjected to the transverse tension/compression of the flanges of the double-tee profile and the beam web and column under shear actions. Because of the complexity of the obtained theoretical formulations, it has been necessary to derive simplified equations whose coefficients have been calibrated against the overall response of the numerically simulated connections. Basing on such statements, it is clear that, even though the proposed equations allow to have a reliable prediction of the flexural strength and initial stiffness of the studied connection nevertheless, they do not allow to really account for the local behaviour of the single nodal components. This is the reason why one of the steps of the research activity consists of studying singularly all the components of the CHS to through-all double-tee connections aiming at assembling all the components to foresee the behaviour of the whole joint.

Within this framework, this paper deals with the study of the component consisting of the "plate transversally welded to the column in tension/compression". Such a topic is not a novelty since Voth [15] has already investigated it, also proposing a formulation for the strength prediction. Nevertheless, his approach consisted of calibration against experimental and numerical results of regression coefficients of an existing formula ([16], [17]) for tubes with

plates externally welded to the column, without adapting the theoretical approach to the specificities exhibited by the connection with through plate.

The present study is a preliminary work for characterizing the behaviour of the nodal component between CHS profiles and through-all plates under tension/compression forces and it is composed of experimental and numerical activities. The experimental campaign consisted of performing three monotonic and three cyclic tests on CHS to through-all plates specimens differing for the geometric properties of the connected elements. Afterwards, numerical models of the tested specimens have been modelled thanks to finite element software and have been validated against the experimental results. As future developments, the validated numerical models will be exploited to perform parametric analyses to investigate a wide range of geometrical properties of the studied CHS to through-all plate connections, aiming at proposing design equations meant to predict the strength and stiffness of the analysed component.

## 2 EXPERIMENTAL ACTIVITY

Aiming at studying the component highlighted in the introduction, three monotonic and three cyclic tests have been performed on specimens having as members circular hollow section profiles and through-all plates (Figure 1).

Figure 1: Analysed connection and experimental set-up

The examined specimens differ for the geometric properties of the connected profiles: the first connection is characterised by a tubular member with a diameter equal to 168 mm, thickness 6 mm, length 450 mm and by a 100 mm width, 30 mm thick and 350 mm length through-all plate; the second specimen is characterised by a CHS with a diameter equal to 219.1 mm, thickness 5 mm, length 500 mm and by a through-all plate with a width of 150 mm, the thickness of 20 mm and length of 350 mm; the third specimen has a tubular member with a diameter equal to 273 mm, thickness 6 mm, length 500 mm and a 160 mm width, 20 mm thick through-all plate with length equal to 400 mm. The plates have been properly selected in order to be ideally representative of the flanges of double-tee profiles (IPE200, IPE300 and IPE330 for the three specimens, respectively) of a CHS to through-all -beam connection.

In order to ensure the plates could pass through the CHSs, the tubular members have been cut with a tolerance of 2 mm around the imprint of the shape of the plates, while the welds consist of single-sided full-penetration butt welds chamfered with an angle equal to 30° adopting the Metal Inert Gas (MIG) welding technique, as suggested by EN 4063-131 provision [18].

The basic material properties of the steel members, characterised by a S275JR steel grade, have been defined by tension coupon tests obtained by the base metal of the specimens.

The testing rig has been conceived in such a way to apply the force at the upper end of the plate employing a vertical actuator (load capacity of 2000 kN in tension and 3000 kN in compression) which is fixed to a rigid steel reaction frame constrained at its base to the strong laboratory floor.

In the test layout, the CHS has been placed horizontally, and its ends have been restrained thanks to steel supports conceived to fix all the degrees of freedom and bolted to the rigid floor of the ITALSIGMA machine (Figure 1). The monotonic and cyclic tests consisted of applying displacements at a rate of 0.5 mm/min until 10 mm displacement, 1 mm/min between a displacement of 10 mm and 20 mm, and 2 mm/min for displacements higher than 20 mm. The specimens have been equipped with 5 LVDTs to monitor not only the vertical displacements but also the horizontal displacements of the supports in order to prove they behave as fixed supports.

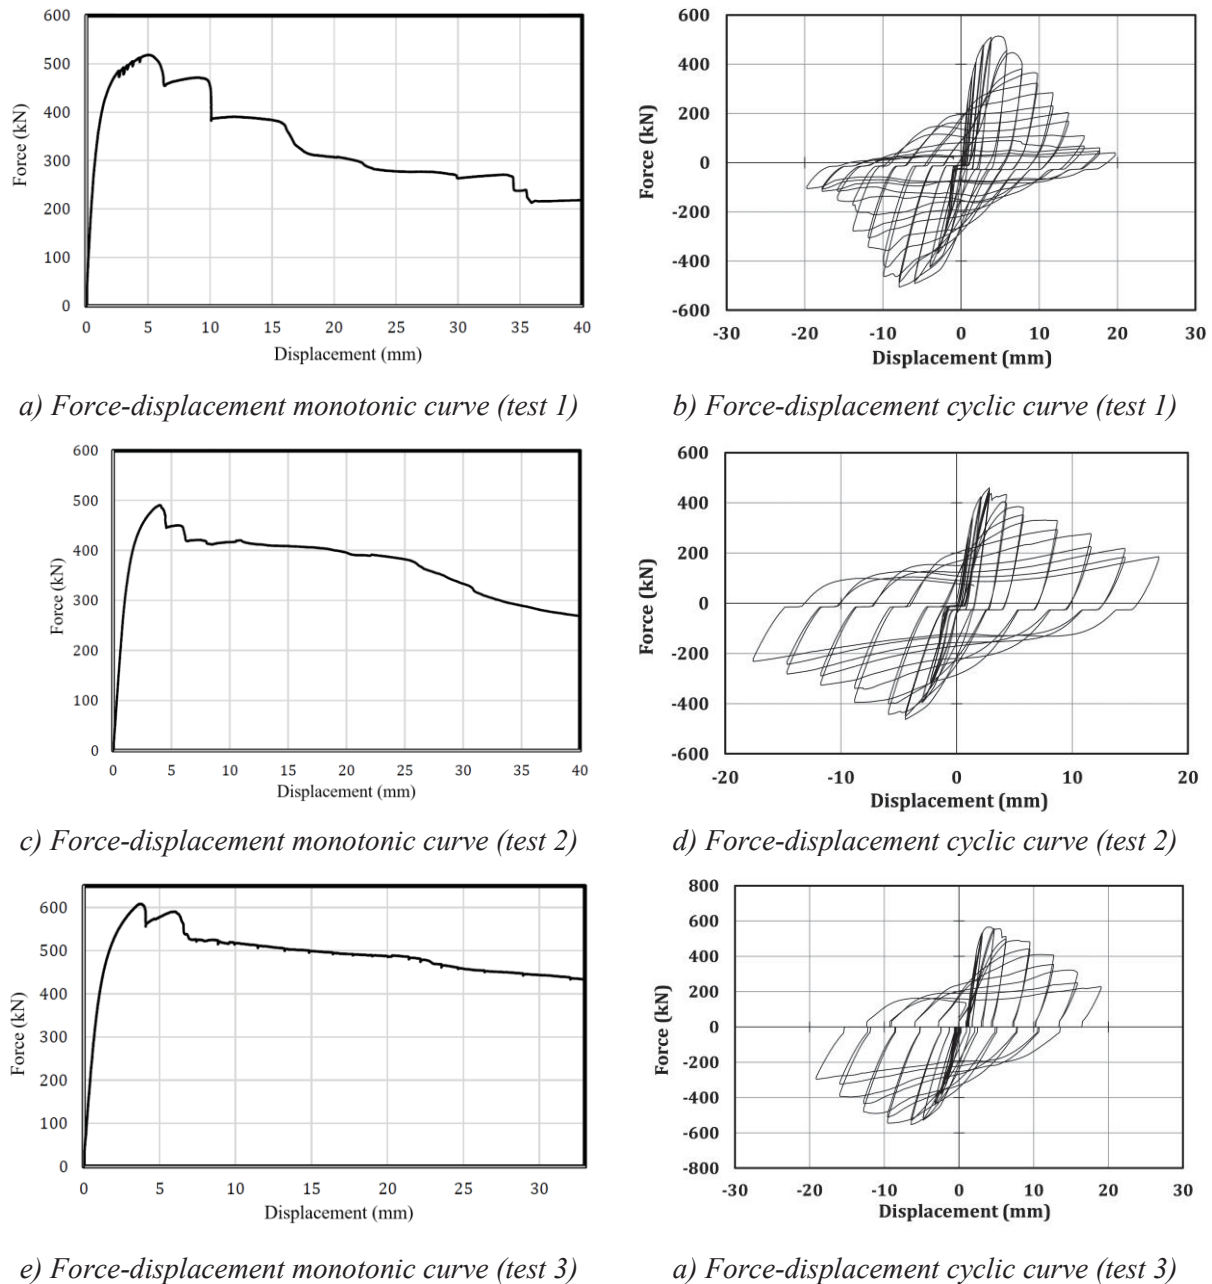

Figure 2: Experimental tests

In Figure 2 the force-displacement curves of the specimens are presented. The maximum forces withstood by the monotonically loaded connections are equal to 518 kN, 491 kN and 608 kN, respectively, for the three specimens, and in all the cases, the maximum strength capacity has been achieved for displacements lower than 5 mm. Instead, the maximum strength experienced by the connections subjected to the cyclic histories are equal to 521 kN, 466 kN and 570 kN, respectively, for the three specimens.

All the specimens collapsed because of the transverse crushing of the tube consistently with the deformed configuration analysed by [12].

### 3 NUMERICAL ACTIVITY

This paragraph is devoted to validating the numerical models of the tested specimens thanks to the finite element (FE) software Abaqus [19].

The geometric characteristics of the specimens have been properly modelled, except for the welds, which have been substituted by Tie contacts between the plate and the tubular profile. Instead, the definition of the mechanical properties has been based on the tension coupon tests; for the sake of clarity, the stress-strain laws have been modelled according to the quadri-linear relationship proposed by Faella [20] with Young's modulus of 210000 MPa and a Poisson's ratio equal to 0.30.

In the FE software, the specimens have been modelled together with the rigid floor of the testing rig and the fixed supports, as given in Figure 3a.

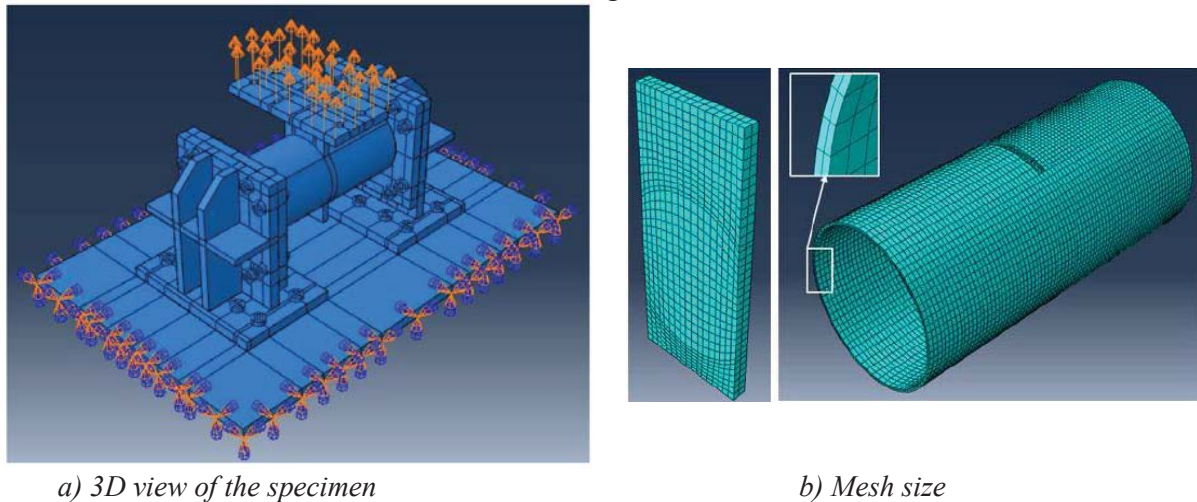

Figure 3: FE model

"Hard" contacts for normal behaviour and frictionless contacts for the tangential behaviour have been applied among the bolts and the plates to which they are connected with; Tie contacts have been employed to model not only the welds between the through-plate and the CHS profile, but also the welds among the plates of the fixed supports. In order to account for the damage evolution, in the numerical model, an equivalent plastic displacement at fracture equal to 4.8 mm has been considered according to the suggestions of [21], [22].

C3D8-type (8-node linear brick) elements with a size equal to 5 mm have been used to mesh the members (Figure 3b).

Referring to Eurocode 3 part 1.5 [23] and according to the construction tolerances provided by EN10034 [24], the imperfection related to the beam-plate attachment, which promotes the local buckling of the tubular profile, has been embedded in the numerical model.

The numerical model has been validated against the experimental results by loading the end of the plate with the same monotonic displacement histories to which the real-scale spec-

imens were subjected. At the end of the simulations, carried out by adopting a static solver, it has been possible to observe the consistency of the failure modes exhibited by the FE models with the experimental observations and also the good prediction of the force-displacement curves, as shown in Figure 4.

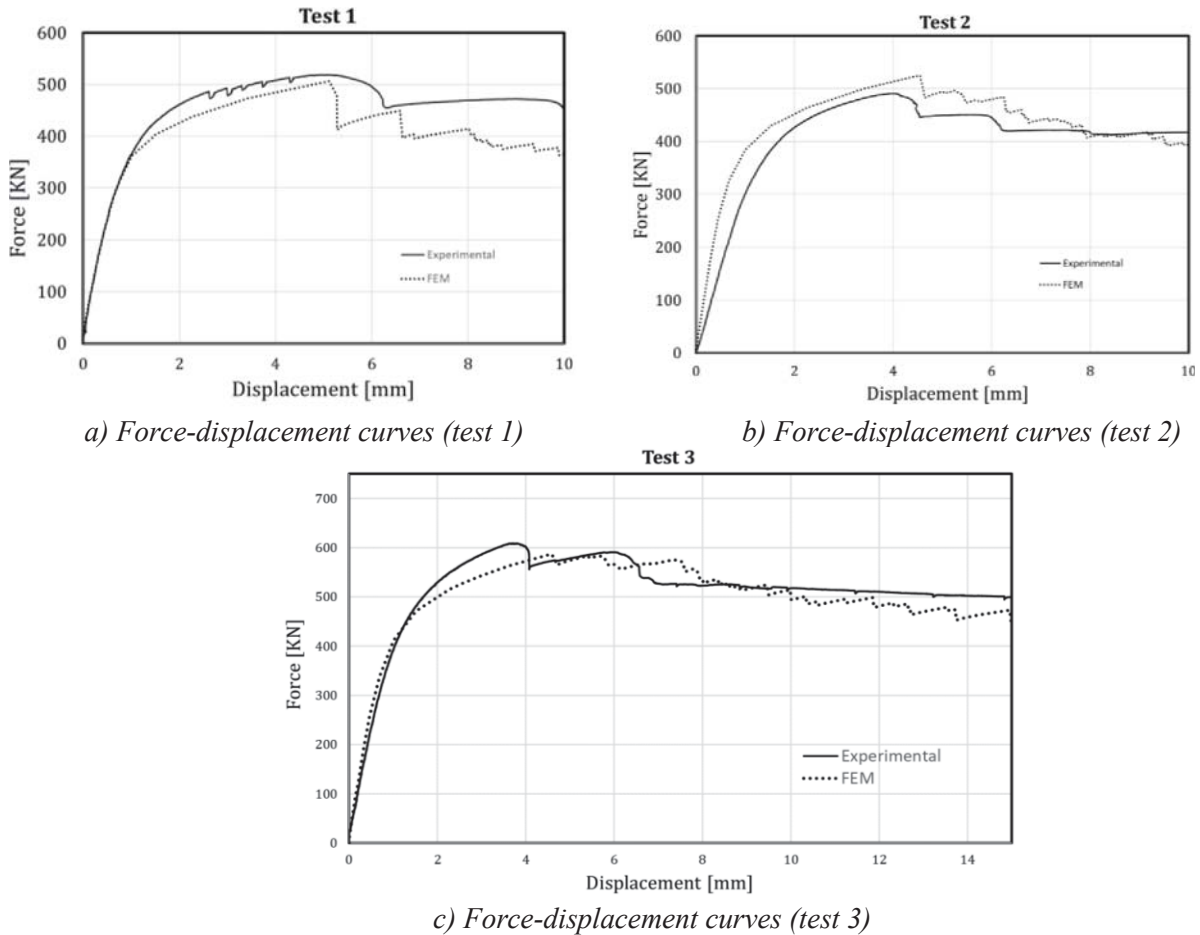

Figure 4: Experimental versus FE results

## 4 CONCLUSIONS

The present work is devoted to studying one of the components of CHS to through-all I-beam connections; in fact, the attention has been focused on the analysis of the plate transversally welded to the circular tubular profile in tension/compression since this component is supposed to behave as the flanges of the double-tee beam welded to the CHS member.

The research efforts consisted in performing experimental tests and numerical simulations. The main conclusions are:

1. the experimental activity has shown that the developed collapse mechanism exhibited by the analysed component is consistent with the supposed theoretical mechanism proposed by [12];
2. a numerical model of the tested specimens has been validated against the experimental results.

Starting from the validated numerical model, the future research efforts will be devoted to the study of a wider range of CHS to through-all plate connections characterized by different geometrical properties. The ultimate aim of the present research activity is to propose design formulations able to foresee the strength and stiffness of the analysed component.

## ACKNOWLEDGEMENTS

The authors want to express their gratitude to Dr. Eng. Francesco Perri and Eng. Ciro Esposito for the help provided during the experimental activity.

## SEISMIC RESPONSE OF INNOVATIVE CFS WALLS BRACED WITH UHS STEEL BARS: EXPERIMENTAL INVESTIGATION

Alessia Campiche<sup>1</sup>

<sup>1</sup> Department of Structures for Engineering and Architecture, University of Naples “Federico II”, Italy

e-mail: alessia.campiche@unina.it

---

### Abstract

*Advantages of Cold Formed Steel (CFS) structures are now well known all over the world. The new goal is represented by the improvement of structural performances, in order to build higher and safer constructions in seismic area. To this aim, in the framework of an Italian project in cooperation with Lamieredil S.p.A. company, the University of Naples “Federico II” developed a new Lateral Force Resisting System (LFRS), made of CFS frame braced by Ultra High Strength (UHS) steel bars in “V” configuration. Three different configurations of the LFRS, with increasing lateral capacities, were designed, and tested under monotonic and reversed cyclic load protocols at the Lab of the Department of Structures for Engineering and Architecture. In total, five tests on full scale 2400x2800 mm<sub>2</sub> (length x height) were carried out. The paper provides all the details on the full-scale wall tests and discusses the obtained results. Moreover, a test-based evaluation of behaviour factor is presented.*

**Keywords:** LWS system, CFS structure, Seismic behaviour, Full-scale test, Behaviour factor.

---

## 1 INTRODUCTION

Many Italian research projects, numerical and analytical studies demonstrated the ability of steel systems to show very good structural [1-16].

The increasing market demand for high-performance and low-cost constructions oriented the choice of the last decades to a competitive and eco-friendly solution: Lightweight Steel (LWS) systems made of Cold-Formed Steel (CFS). In this field the University of Naples “Federico II” was really active [17-25] and in this perspective an Italian Research Project, named as ECCEISA [1], has recently finished, in which the main aim was the development of an innovative LWS system with higher structural, energetic and environmental performances. The core of the project was the evaluation of seismic and thermal performances of a wall system braced with pre-tensioned Ultra-High-Strength (UHS) steel bars.

The innovative wall system is mainly composed of: (1) UHS steel bracing; (2) pre-tensioning devices; (3) chord studs; (4) tracks; (5) hold-downs; (6) blocking profiles and flat straps.

The UHS steel bracing consists of two diagonal braces, which are pre-tensioned dog bone shaped round bars having thread ends to allow their connection and pre-tensioning. For the chord studs, a back-to-back C section was selected, while for tracks a box section was chosen. The pre-tensioning device is a U shape profile connected to the hold-down through a cylindrical hinge, which allows the rotation in the plane of the wall.

A UHS steel ( $f_y=1300$  MPa,  $f_u=1450$  MPa) is adopted for the diagonal braces, while chord studs, tracks, blocking and flat straps are made of S280 GD+ Z steel grade, and devices for pre-tensioning and hold-downs are made of S355 steel grade ( $f_y=355$  MPa,  $f_u=470$  MPa). More details about the innovative wall and the design phase are available in [26].

The effectiveness and the limitations of the innovative wall system were validated through an extensive experimental campaign carried out at Laboratory of the Department of Structures for Engineering and Architecture of University of Naples “Federico II”, which consisted of small-scale tests on materials and nut-bar assemblies and full-scale wall tests. This paper describes in details the full-scale wall tests and the obtained results.

## 2 EXPERIMENTAL TESTS

The main core of the research project was the evaluation of seismic behaviour of the innovative wall system. To this purpose, five tests, including three monotonic tests and two cyclic tests, were carried out on full-scale 2400 mm long and 2800 mm high wall specimens. Two configurations of the innovative wall system have been investigated, which were representative of Light (L) and Medium (M) configurations developed. The label defines the specimen typology. Namely, the first letter indicates the test typology (M for monotonic test and C for reversed cyclic test), the second letter is referred to the wall specimen (L for specimen representative of Light configuration and M for specimen representative of Medium configuration) and the number represents the test number; e.g. M\_L1 means the monotonic test no. 1 carried out on the specimen representative of the Light wall configuration. Both configura-

ration specimens are represented in Figure 1. In both configurations and for both protocols used, the bars were pre-tensioned before starting the test via a torque wrench.

The test program is summarized in Table 1, in which the load type, loading protocol and number of tests are shown.

L Configuration wall tested

M Configuration wall tested

Figure 1 Specimen tested

Table 1 Test matrix for the monotonic and cyclic tests on full-scale walls

Test Label	Wall type	Load Type	Protocol	Number of tests
M L	Light	Monotonic	-	2
M M	Medium	Monotonic	-	1
C L	Light	Cyclic	CUREE	1
C M	Medium	Cyclic	CUREE	1

An available steel frame set-up for in-plane wall tests was modified and used for the experimental activity (Figure 2). The wall prototype was restrained to the laboratory strong floor by the bottom beam, which has a  $300 \times 180 \times 30$  (width  $\times$  height  $\times$  thickness) rectangular hollow section. Horizontal loads were transmitted to the wall through the loading beam, which has a  $200 \times 120 \times 10$  mm (width  $\times$  height  $\times$  thickness) rectangular hollow section. The out-of-plane displacements of the wall were restrained by two steel portal frames equipped with roller wheels. The tests were performed by using a hydraulic actuator having a stroke displacement of 500 mm and a load capacity of 500 kN. A sliding-hinge was placed between the loading actuator and the loading beam, in order to avoid vertical load components.

Figure 2 Wall test set-up

Six LVDTs and two potentiometers were used to measure the specimen displacements. In particular, three LVDTs (L1, L2 and L3) were installed to record hold-down horizontal and vertical displacements, two LVDTs (L4 and L5) for the upper beam vertical displacements, one LVDT (L6) for wall vertical displacements and two potentiometers (P1 and P2) for wall horizontal displacements. The strains in selected points of the diagonal bars and studs were recorded by means of fourteen strain-gauges. Two strain-gauges were installed on each diagonal (SG1 and SG2 placed near the middle section, where the diameter is reduced, and SG3 and SG4 placed where the section is maximum), four strain gauges were placed on the intermediate stud in two sections (SG5 and SG6 placed on the upper section, SG7 and SG8 on the lower section) and six strain gauges were placed on the right chord stud (SG9, SG10 and SG11 placed on the upper section and SG12, SG13 and SG14 placed on the lower section). The instrumentation pictures are shown in Figure 3. A load cell was used to measure the applied loads.

Figure 3 Photographs of wall test instrumentation

## 2.1 Monotonic tests

Monotonic tests were carried out with displacements imposed at a rate of 0.10 mm/s until the collapse of specimens occurred. The data were recorded with a sampling frequency equal to 10 Hz.

Three monotonic tests were carried out on two L and one M walls. Results for M\_L2 and M\_L1 specimens are provided in **Errore. L'origine riferimento non è stata trovata.**, in term of load (H) vs. inter-storey drift ratio (dr) curves. The displacements used for the evaluation of inter-storey drifts were measured by potentiometer P1, whereas load was provided by load cell.

Numerical values are provided in Table 2, according to the following parameters:

- $H_0$ : wall strength corresponding to the end of the Phase (1);
- $H_e$ : wall conventional yield strength evaluated according to ECCS procedure [9];
- $H_y$ : wall strength corresponding to the end of the Phase (2);
- $H_p$ : maximum recorded load corresponding to the end of the Phase (3);
- $d_e$ : yield displacement evaluated according to ECCS procedure [27];
- $d_{max}$ : maximum displacement, evaluated in correspondence of  $H_p$
- $d_{r,e}$ : yield inter-storey drift ratio, equal to  $d_e/h$ ;
- $d_{r,max}$ : maximum inter-storeydrift ratio, equal to  $d_{max}/h$ ;
- $k_e$ : initial elastic stiffness corresponding to the tangent to initial part of the response curve, equal to  $H_e/d_e$ ;
- $\mu$ : ductility, equal to the ratio between the conventional ultimate displacement and displacement at conventional elastic limit load  $d_{max}/d_e$  or equally  $d_{r,max}/d_{r,e}$ .

Globally, for all the specimens the monotonic response showed a three-phase lateral behaviour. In particular, the curves are characterized by three different branches: (1) the first linear branch with a stiffness  $k_e$ ; (2) once achieved  $H_0$ , the second branch characterised by a linear response having a stiffness smaller than  $k_e$ ; (3) once achieved  $H_y$ , the third branch characterised by a nonlinear response.

M\_L2 and M\_M1 specimens showed the same collapse due to the tension failure of the bar, whereas in M\_L1 specimen, during the phase (3), nut failure happened, since only one 12 property Class nut was employed. The collapse mechanism observed in M\_L2 test is provided in Figure 5. Comparing the results of two nominal identical tests, M\_L1 and M\_L2, can be noticed that:

- small differences in terms of  $H_y$  and  $H_p$  were revealed, equal to about 3% and 1%, respectively;
- high differences in term of inter-storey drift ratios achieved were registered, equal to about 19 and 51% for  $d_{r,e}$  and  $d_{r,max}$ , respectively, since the M\_L1 showed a brittle nut failure.

Results of M\_L2 test

Results of M\_M1 test

$d_{r,max}$ [%]	3.11	6.39	4.25
$k_e$ [kN/mm]	3.76	3.00	5.25
$\mu$ [-]	3.28	5.42	4.99

## 2.2 Reversed cyclic tests

Cyclic tests were carried out by adopting a loading protocol known as “CUREE ordinary ground motions reversed cyclic load protocol” developed for wood walls by Krawinkler et al. [28], modified according to the prescription given in Velchev et al. [29]). The general cyclic protocol is summarized in Figure 6. Since  $\Delta$  obtained from monotonic results was not really different between L and M configuration, the same specific protocol was adopted for both C\_L1 and C\_M1 tests.

Figure 6 CUREE cyclic protocol adopted for C\_L1 and C\_M1 tests

The cyclic curves obtained (Figure 7) showed a behaviour rather symmetrical. The three-phase behaviour also characterized the cyclic response, but only in pushing. In fact, for both specimens collapse happened immediately reached the Phase (3) in pushing (positive range), whereas in pulling (negative range) the Phase (3) was not reached. Table 3 summarizes numerical results obtained. Both C\_L1 and C\_M1 specimens had the same collapse due to the tension failure of the bar, as shown in Figure 8.

Cyclic response for C\_L1 test

Cyclic response for C\_M1 test

### 2.3 Discussion of results

The global behaviour of the innovative wall was evaluated through the measurements obtained during monotonic and cyclic tests. Thanks to potentiometers P1 and P2 the wall lateral behaviour was individuated. More considerations can be done, if a comparison between monotonic and cyclic results of nominally identical specimens (Figure 9) is conducted and, in particular, considering M\_L2 and M\_M1 as monotonic tests and C\_L1 and C\_M1 as cyclic

tests. Results of M\_L1 were not considered, since it showed nut failure, instead of tension collapse of bar. It can be observed that:

- Cyclic protocol does not affect greatly the resistance of wall, in fact, monotonic and cyclic  $H_p$  difference is equal to about 5% and 7% for L and M configuration, respectively;
- Cyclic protocol greatly affects the displacement capacity of wall, indeed the ductility of wall. In fact, difference in term of  $d_{r,max}$  is equal to about 92% and 65% for L and M configuration, respectively;
- Monotonic and cyclic elastic stiffness exhibited similar values for both L and M configurations (3.00 and 3.49 kN/mm for L configuration and 5.25 and 5.25 for M configuration).

The data obtained from LVDTs make possible the evaluation of hold-down stiffness and, in particular, three stiffnesses were evaluated: vertical stiffness  $k_v$ , horizontal stiffness  $k_h$  and rotational stiffness  $k_r$ . The adding source of deformability  $1/k_{tot}$  produced by hold-downs was evaluated, according to Equation 1, and it was in the range  $2-3 \times 10^{-5}$ .

Equation 1

$$\frac{1}{k_{tot}} = \frac{1}{k_1 + k_2 + 2k_h}$$

Where  $k_1$  and  $k_2$  are the adding source of global stiffnesses to vertical translation and rotation offered by hold-downs and are evaluated with Equation 2 and Equation 3.

Equation 2

$$k_1 = \frac{k_r}{h^2}$$

Equation 3

$$k_2 = \frac{L^2}{h^2} k_v$$

Therefore, from the results, it can be assumed that hold-downs are rigid and offer a perfectly rigid restrain to the system.

Furthermore, through the local measurements given by SG, it was possible to evaluate the distribution of stresses and quantify the horizontal load absorbed by the frame and by the bracing. According to results, the contribution offered by the frame is really important, absorbing 50% of total horizontal load applied to the wall.

As far as inter-storey drift ratios are concerned, experimental values achieved were in the range 2.6%-6.8% and were always higher than design limit drift ratio considered (2.5%).

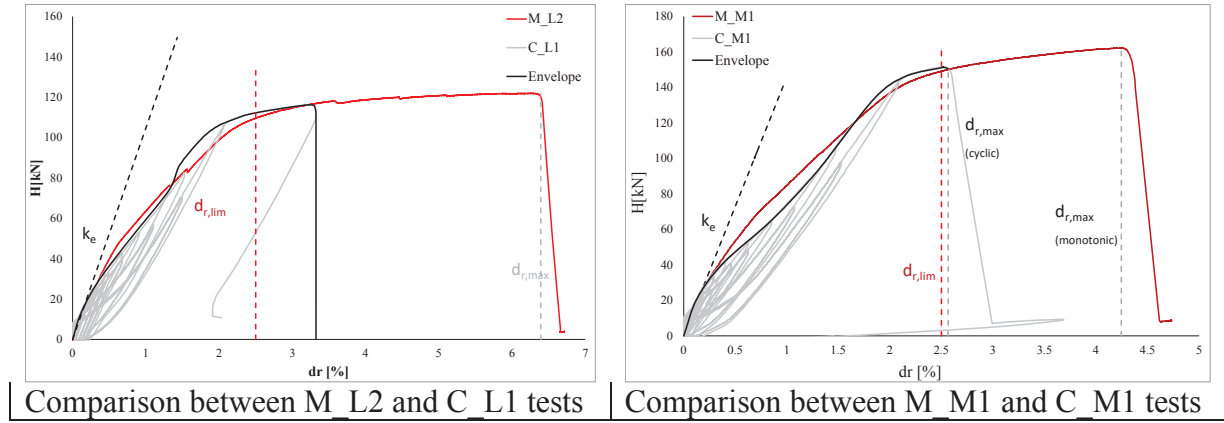

Figure 9 Comparison between monotonic and cyclic results

### 3 TEST-BASED BEHAVIOUR FACTOR EVALUATION

A preliminary experimentally based evaluation of behaviour factor was conducted. The behaviour factor ( $q$ ) was defined by the ductility-related ( $R_d$ ) and overstrength-related ( $R_0$ ) modification factors.

In particular, the ductility-related modification factor  $R_d$  represents the ability of the structural system to dissipate seismic energy, whereas the overstrength-related modification factor  $R_0$  represents the reserve of strength of the designed structure. The behaviour factor ( $q$ ) can be estimated using Equation 4, as given in Uang [56]:

Equation 4

$$q = R_d \cdot R_0$$

Since fundamental periods for this structural system is generally in the range 0.1-0.5 s, the ductility-related force modification factor  $R_d$  can be evaluated according to the principle of equal energy (Equation 5):

Equation 5

$$R_d = \sqrt{2\mu - 1}$$

where  $\mu$  is the ductility.

The  $R_0$  factor can be evaluated through the formulation provided by Mitchell et al. [57]:

Equation 6

$$R_0 = R_{sd} \cdot R_\phi \cdot R_{yield} \cdot R_{sh}$$

where  $R_{sd} = H_c/H_d$ , with  $H_c$  and  $H_d$  design wall resistance and seismic demand, respectively;

$R_\phi = H_{yn}/H_c$ , with  $H_{yn}$  design resistance associated by yielding of the braces multiplied by the safety factor  $\gamma_{M0}$ ;

$R_{yield} = H_y/H_{yn}$ , with  $H_y$  experimental yielding resistance;

$R_{sh} = H_p/H_y$ , with  $H_p$  experimental wall strength.

In order to neglect the design overstrength, in this study the assumption of  $R_{sd} = H_c/H_d = 1$  has been made. Therefore, the  $R_0$  factor can be evaluated through Equation 7:

Equation 7

$$R_0 = \frac{H_{yn}}{H_c} \cdot \frac{H_y}{H_{yn}} \cdot \frac{H_p}{H_y} = \frac{H_p}{H_c}$$

Table 4 shows the values of the behaviour factors obtained by the test-based evaluation. For the cyclic tests  $R_0$ ,  $R_d$  and  $q$  were evaluated considering the average values in pushing and pulling phases. The test M\_L1 was not considered since it showed a brittle premature failure. The average test-based values of behaviour factors are in the range of 3.09- 4.07 for the L Configuration and 3.67- 4.07 for the M Configuration. On the safe side, it can be concluded that a value of behaviour factor equal to 3 can be assumed for the L configuration and a value equal to 2.5 for the M Configuration.

Table 4 Test-based evaluation of behaviour factor

Test	M_L2	M_M1	C_L1	C_M1
$\mu$	5,42	4,99	3,61	2,95
$R_d$	3,14	3,00	2,49	2,21
$R_0$	1,30	1,22	1,24	1,14
$q$	4,07	3,67	<b>3,09</b>	<b>2,53</b>

#### 4 CONCLUSIONS

In the framework of an Italian research project, developed in cooperation with Lamieredil S.p.A. Company, an innovative wall system was developed and tested. The experimental tests were performed at the Laboratory of DIST (Department of Structures for Engineering and Architecture) of the University of Naples “Federico II”. The experimental results showed satisfactory seismic responses, in line with the theoretical previsions, if all the prescriptions are followed. In particular, if not well designed, the nut used for the bar pre-tensioning can cause a premature failure of the system and the displacement capacity is strongly reduced. The walls, in which all the design prescriptions were respected, exhibited satisfactory force and displacement capacity.

### Abstract

*Lightweight Steel (LWS) buildings fabricated with cold-formed steel profiles are a viable alternative to traditional reinforced concrete or masonry buildings for low to mid-rise constructions. The current edition of Eurocode 8 does not provide seismic design guidelines for them in Europe. This paper presents a new seismic design criterion for these buildings, which is proposed to be added in the next edition of Eurocode 8. The criteria include design guidelines for lateral force resisting systems that are most common to LWS buildings. These systems include: CFS strap braced walls and CFS shear walls with steel sheets, wood, or gypsum sheathing. A brief overview of these guidelines and the relevant background information is provided in this paper. Then these guidelines are validated with a numerical study on several building archetypes. Archetypes are designed following the proposed seismic design criteria and analyzed under the suite of forty-four earthquake records. Archetypes are analyzed using both nonlinear pushover analysis and incremental dynamic analysis. Based on the analysis results, their collapse probability is gauged to judge the level of protection against seismic hazard provided by the proposed design criteria.*

**Keywords:** Eurocode 8, seismic design criteria, lightweight steel structures, lateral force resisting systems, cold-formed steel

## 1 INTRODUCTION

Lightweight Steel (LWS) buildings are low to mid-rise constructions fabricated with cold-formed steel (CFS) frames. In Europe, the use of these buildings is limited in regions with medium-to-high seismic hazard. This is mainly due to the absence of seismic design guidelines for these types of building in European building codes: Eurocodes. In particular, the Eurocode 8 part 1: EN 1998-1 [1] deals with the seismic design of building structures. The current edition of EN 1998-1 was published back in 2004 and it does not provide a specific seismic design criterion for LWS buildings, which can utilize their energy dissipation potential. Therefore, the main crux of this paper is the proposal of the seismic design criterion for the LWS buildings, which could be included in the upcoming second edition of EN 1998-1.

Design rules for LWS buildings are already available in North American Standard for seismic design of cold-formed steel structures: AISI S400 [2] for use in the USA, Canada, and Mexico. Apart from this, no other building code in the world provides seismic design guidelines for LWS buildings, which can utilize their energy dissipation potential. The design rules given by AISI S400 follow the capacity design approach. For all LFRS covered by AISI S400, it defines energy dissipation mechanisms of dissipative components, provides overstrength requirements concerning non-dissipative components and gives a value of response modification factor accounting for system inherent overstrength and ductility. LWS buildings are not explicitly covered by current edition of EN 1998-1 and only LWS buildings braced with strap braced walls could be designed as common Low dissipative steel structures belonging to Ductility class low (DCL) structures made of Class 4 cross-section profiles, for which EN 1998-1 allows a behavior factor of 1.5 to be used in the design.

The main aim of the paper is to enlighten the readers and users of Eurocodes about the background information on the research works [3–4, 13–22, 5, 23–27–6–12] and the reference design standards, already being used in some parts of the world, which formed the basis of proposed seismic design guidelines for LWS buildings. The design guidelines are explained and its validation through a numerical study on several LWS building archetypes is shown. The second edition of EN 1998-1 will provide rules for LWS buildings laterally braced with four different types of LFRS's: CFS strap braced walls (Figure 1); CFS shear walls with steel sheet sheathing (Figure 2), or wood sheathing, or gypsum sheathing.

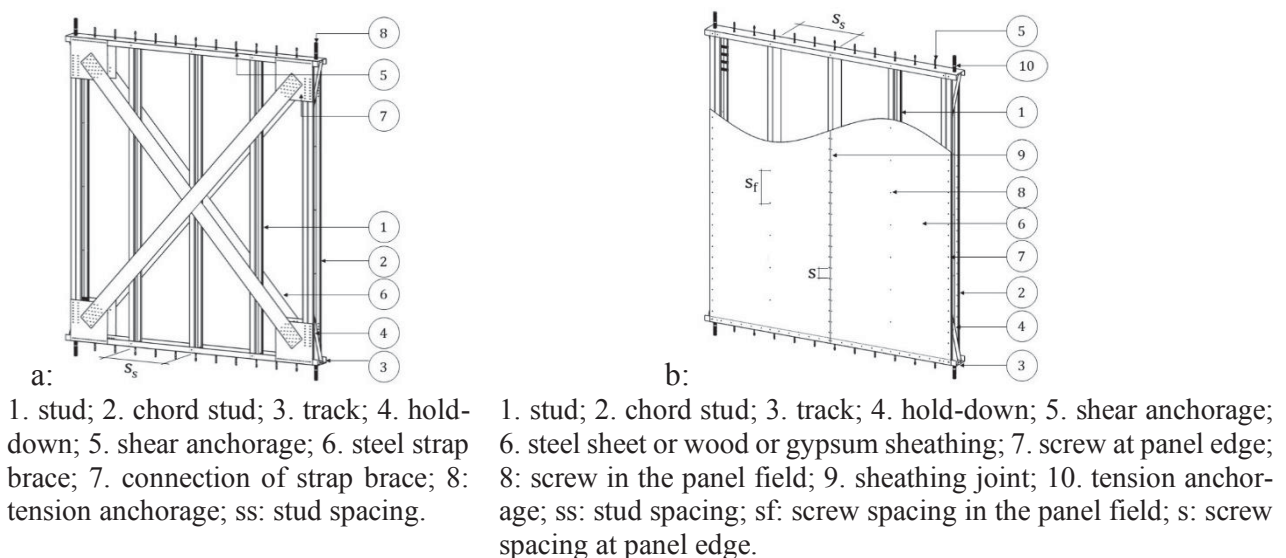

Figure 1 a: CFS strap braced wall; b: CFS Shear walls

## 2 DESIGN FRAMEWORK OF 2ND EDITION OF EN 1998-1

The second editions of Eurocode 8: EN 1998-1 would allow achieving three levels of ductility in building structures equipped with a certain type of LFRS. These levels include:

1. DC1: Low Dissipative structural behavior.
2. DC2: Medium Dissipative structural behavior.
3. DC3: High Dissipative structural behavior.

A structure cannot be designed beyond a certain limit of seismic load in the case of DC1 and DC2 Class structures while in the case of DC3 Class structures, there is no limit on the seismic action. In DC2 and DC3 Class structures, the capability of parts of the LFRS (dissipative components) to resist the seismic actions through plastic behavior in dissipative components is taken into consideration during the design process. To ensure the development of plastic mechanisms and subsequent energy dissipation in the dissipative components, specific design requirements are provided for them. For non-dissipative components of LFRS, design requirements ensure an overstrength in them to safeguard against failure. The overall design process of the second edition of EN 1998-1 would be a capacity design process. The design requirements for the dissipative components of CFS LFRS's belonging to both DC2 and DC3 Class structures would be the same. On the other hand, overstrength requirements for the non-dissipative components would be different for DC2 and DC3 Class structures.

In contrast to the DC2 and DC3 Class structures, the DC1 Class structures would not be required to follow any specific design and overstrength requirements. The design of individual components of DC1 class structure can be carried out according to EN 1993-1-3 [28], and other relevant European building standards [29–30]. Therefore, DC1 class structures would have a limited ductility capacity, and a lower value of behavior factor ( $q$ ) equal to 1.5 is proposed for them. Meanwhile, in the case of DC2 and DC3 class structures, the ability of structures to dissipate energy through their plastic behavior is accounted for, therefore higher values of  $q$  are proposed for them. The values of the behavior factor for DC2 and DC3 Class structures are derived from the studies [31–32] conducted following the FEMA P695 methodology [33].

Apart from providing special design requirements for DC2 and DC3 Class structures, the second edition of EN 1998-1 will also provide some general rules. These general rules include the limitation on the aspect ratio (height-to-length ratio) of the walls, which is fixed equal to 2.0 for all types of LFRS's. To have a sufficient deformation capacity of connections in the walls, the new version of EN 1998-1 would require the design shear resistance of the screws to be greater than 1.2 times the design bearing resistance of the steel structural member, or the design embedment resistance of wood or gypsum panels (in case of shear walls with panels), or the design net area resistance of the strap brace (in case of strap brace walls). This rule has been derived from the already existing guidelines in EN 1993-1-3 [28] for the shear design of connections made with screws.

## 3 DESIGN REQUIREMENTS FOR DISSIPATIVE COMPONENTS

The second edition of EN 1998-1 would provide specific rules to calculate the design strength of the LFRS in the case of DC2 and DC3 class structures. In addition to these design rules, the code will also provide geometrical and mechanical requirements for the components and parts of the shear walls, which must also be fulfilled to achieve the desired energy dissipation response in the walls. The requirements are defined based on the already existing geometrical and mechanical limitations on the permitted wall configurations given in AISI S400 [2].

For strap braced walls, the yield resistance ( $N_{pl, Rd}$ ) of the gross cross-section of the strap braces should be greater than the design value of the axial force in the strap brace in the seismic design situation and the design net area resistance ( $N_{u, Rd}$ ) of the strap brace. This requirement

ensures the formation of plastic mechanism in steel straps before the net section failure happens in strap connection to the wall frame. The values of  $N_{pl,Rd}$  and  $N_{u,Rd}$  can be obtained from other relevant parts of Eurocode 3 [30].

In case of shear walls with steel sheet sheathing, the in-plane lateral resistance ( $R_{c,Rd}$ ) corresponding to the strength of the sheathing connection within the effective sheathing strip should be greater than the design value of the lateral force acting on the shear wall in the seismic design situation, but it should be less than, the design yielding resistance of the effective sheathing strip ( $R_{y,Rd}$ ).  $R_{c,Rd}$  and  $R_{y,Rd}$  are evaluated based on the effective strip method (ESM) proposed in [31]. ESM was calibrated based on the large amount of steel sheathed shear walls tested in USA and Canada over recent years. In the original proposed ESM [31],  $R_{c,Rd}$  is calculated according to Eq. (1), which relies on the formulation of North American specification for the design of CFS structural members AISI S100 [32] for the calculation of single sheathing connection bearing strength ( $F_{b,Rd}$ ).

$$R_{c,Rd} = 1.33nF_{b,Rd} \cos \left( \text{Arctan} \left( \frac{h}{w} \right) \right) \quad (1)$$

where  $F_{b,Rd}$  is the bearing resistance of the sheathing connection,  $n$  is the number of sheathing connections in the effective width,  $h$  is the height of wall and  $w$  is the length of wall. AISI S100 provides a different relationships for  $F_{b,Rd}$  than the one provided in Eurocode 3 [28]. Eq. (2) and (3) gives the formulations of  $F_{b,Rd}$  given by AISI S400. If  $t_1/t \leq 1.0$ , then Eq. (2) is used or if  $t_1/t \geq 2.5$ , then Eq. (3) is used else  $F_{b,Rd}$  can be linearly interpolated between the values obtained from Eq. (2) and (3).

$$F_{b,Rd} = \min(2(t_1^3 d)^{\frac{1}{2}} f_{u,1}; 2.7 t_1 d f_{u,1}) / \gamma_{M2} \quad (2)$$

$$F_{b,Rd} = \min(2.7 t_1 d f_{u,1}) / \gamma_{M2} \quad (3)$$

where  $f_{u,1}$  and  $f_u$  are the ultimate tensile strength of the framing elements and the sheathing, respectively;  $t_1$  is the thickness of stud or track;  $d$  is the nominal diameter of screws and  $\gamma_{M2}$  is the partial safety factor equal to 1.25. Contrarily in the European standard for cold-formed steel design (EN1993-1-3 [28]), a different formula is proposed. Authors in their recent study [34] checked the validity of the ESM with  $F_{b,Rd}$  evaluated according to equation given by EN 1993-1-3. The use of the value of  $F_{b,Rd}$  evaluated from equation by EN 1993-1-3 results in underestimation of the wall strength. Therefore, the second edition of EN 1998-1 would require the strength of sheathing connections ( $F_{b,Rd}$ ) to be calculated according to equation (2) and (3), that are taken from AISI S100.

For CFS shear walls with wood or gypsum sheathing, the in-plane lateral resistance ( $R_{c,Rd}$ ) corresponding to the strength of the sheathing connection should be greater than the design value of the lateral force acting on the shear wall in the seismic design situation.

## 4 OVERSTRENGTH REQUIREMENTS

To guard the non-dissipative components of the LFRS's against the failure, an overstrength would be provided in them for use in DC2 and DC3 class structures according to the second edition of EN 1998-1.

### 4.1 DC2 class structure

The overstrength requirements for the DC2 Class structures ensure the formation of the desired energy dissipation mechanism in the dissipative components of LFRS through an overstrength in the non-dissipative components. The overstrength factors are applied using Equation (4) on the non-dissipative components of the LFRS of a DC2 Class structure to verify their strength and stability against the most unfavorable combination of the axial force  $N_{Ed}$ .

$$N_{Ed} = N_{Ed,G} + \Omega N_{Ed,E} \quad (4)$$

where:  $N_{Ed,G}$ , is the axial force in the non-dissipative member due to the non-seismic actions included in the combination of actions for the seismic design situation; and  $N_{Ed,E}$ , is the axial force in the non-dissipative member due to the design seismic action. The overstrength factor for different types of LFRS's is listed in Table 1 along with their behavior factor.

LFRS	q	$\Omega$
Strap braced walls	2.0	1.5
Shear walls with steel sheet sheathing	2.0	1.5
Shear walls with wood sheathing	2.0	1.5
Shear walls with gypsum sheathing	1.7	1.35

Table 1 Behavior and overstrength factors for DC2 Class structures

#### 4.2 DC3 class structures

The overstrength requirements for DC3 class structure are different for each type of LFRS in the second edition of EN-1998-1. For strap braced walls, the brittle components listed in Section 2.1 should be designed with an overstrength computed according to (5).

$$R_d \geq F_{Ed,G} + \gamma_{rm} \gamma_{sh} R_{fy} \quad (5)$$

where,  $R_d$  is the design resistance of the non-dissipative brittle component;  $F_{Ed,G}$  is the design action in the component due to the non-seismic actions included in the combination of actions for the seismic design situation;  $\gamma_{rm}$  is the overstrength factor accounting for the variability of the steel yield strength in the dissipative zones, i.e., ratio between the expected (average) and nominal yield strength, and ranges from 1.20 to 1.45 for lower to higher steel grades,  $\gamma_{sh}$  is the overstrength factor accounting for the hardening in the dissipative zones and is equal to 1.1;  $R_{fy}$  is the plastic resistance of the gross cross-section of the strap braces based on the nominal yield stress of the material as defined in Eurocode 3 [35].

For shear walls with steel sheet sheathing, equation (6) is proposed, which ensures the overstrength in their brittle components.

$$R_d \geq F_{Ed,G} + \gamma_{rm} R_{c,Rd} \quad (6)$$

where  $\gamma_{rm}$  is the overstrength factor, i.e., ratio between the expected (average) and design in-plane lateral resistance of the shear wall, equal to 1.40, and  $R_{c,Rd}$  is the design in-plane lateral resistance of the shear wall evaluated based on sheathing connection strength calculated according to equation (1).

For CFS shear walls with gypsum or wood sheathing, equation (7) is used to provide overstrength in their brittle components.

$$R_d \geq F_{Ed,G} + \gamma_{rm} R_{c,k} \quad (7)$$

where  $\gamma_{rm}$  is the overstrength factor, i.e., ratio between the expected (average) and characteristic in-plane lateral resistance of the shear wall, equal to 1.50, and  $R_{c,k}$  is the characteristic in-plane lateral resistance of the shear wall. Table 2 summarizes the values of  $\gamma_{rm}$  used for the overstrength of DC3 Class structures along with the values of the behavior factor for different LFRS's.

LFRS	q	$\gamma_{rm}$
Strap braced walls	2.5	1.20 to 1.45
Shear walls with steel sheet sheathing	2.5	1.40
Shear walls with wood sheathing	2.5	1.50
Shear walls with gypsum sheathing	2.0	1.50

Table 2 Behavior and overstrength factors for DC3 Class structures

## 5 VALIDATION OF DESIGN CRITERIA

To validate the design rules listed in previous sections, proposed for inclusion in the second edition EN1998-1, a numerical study considering several building archetypes was performed. LWS building archetypes braced with all four types of seismic force-resisting systems were designed as both DC2 and DC3 class structures. Nonlinear FE models for the archetypes were developed in OpenSees software [36]. The seismic performance of the models is evaluated following the FEMA P695 methodology [33].

### 5.1 Building archetypes

A total of eight double-storey residential building archetypes designed as DC2 or DC3 class structures and braced with the four types of LFRS's were selected. The archetypes were assumed to be situated on a soil type C in a medium seismic intensity zone having reference PGA (Peak Ground Acceleration),  $a_{g,R}$ , of 0.2g, which has a 10% probability of exceedance in 50 years. The live load due to residential occupancy was 2.0 kN/m<sup>2</sup>. In addition to permanent loads and live loads, a 1.00 kN/m<sup>2</sup> snow load and 0.35 kN/m<sup>2</sup> wind load were also considered to be acting.

EN 1993-1-3 [28] was used to design the gravity load resisting elements of the archetypes. Current in practice edition of Eurocode 8: EN 1998-1 [1] was used to define the seismic actions on the buildings. The lateral force method was used to obtain the building design base shear ( $F_b$ ), which is mainly the function of building design response spectrum and mass.

The seismic design process of LWS buildings involves the selection of configurations of strap braced or shear walls, that can be used to resist the lateral actions, evaluating the design strength of the wall configurations, and then eventually the total number of the required walls are obtained by dividing the design base shear with the design strength of a single wall. Table 3 lists the design base shear of the archetypes ( $F_b$ ), design strength of the walls ( $R_d$ ), and the number of the walls provided in each planar direction of the archetype.

Archetype Ductility class	Wall name	w x h <sup>1</sup> [m]	q [-]	Fb kN	Rd kN	No. of walls required <sup>2</sup> [-]	No. of walls provided [-]	C/D <sup>3</sup> [-]	D/C <sup>4</sup> [-]
<b>Strap braced walls</b>									
DC2	WLD mod	2.4 x 2.7	2	212.3	43.7	4.9	6	1.235	0.81

<sup>3</sup> Building archetype design capacity to design demand ratio

<sup>4</sup> Building archetype design demand to design capacity ratio

Table 3 Seismic design details of building archetypes

The selected configuration for strap braced walls in the DC3 building archetype has been already tested in an Italian research project [32]. On the other hand, no reference test results were found for the wall, which can only meet the criteria of the DC2 ductility class. Therefore, it was decided to downgrade the DC3 walls in a way that it would become DC2. For this purpose, the chord studs and the hold-down devices have been modified. In this way, the new wall named as WDL mod does not satisfy the design criteria required for the DC3 ductility class but guarantees the fulfillment of the criteria for the DC2.

In the case of steel sheathed shear walls, the selected wall configuration belonging to the DC3 class has already been tested at McGill University in Canada [37] and was named as ST1 -c in the referenced research. On the other hand, DC2 wall configuration is obtained for steel sheathed shear walls similarly to strap braced walls. Likewise, gypsum sheathed shear wall configuration to be used in a DC3 class building is selected from the series of tests carried out at the University of Naples Federico II, Italy within the ELISSA project [32]. The DC3 wall selected from the referenced research was named S\_2400C. While DC2 wall configuration is obtained by modifying the chord studs of the DC3 wall configuration in the case of gypsum sheathed shear walls. The wood sheathed shear wall configuration to be used in a DC3 and DC2 class building archetypes were selected from the series of tests carried out in the USA within the CFS NEES project [38]. The tested wall configuration 14 and 4 in the reference research are used as DC2 and DC3 class walls, respectively.

## 5.2 Numerical modeling and analysis

A three-dimensional numerical model was developed for each archetype in OpenSees software [36]. The nonlinear behavior of building archetypes was represented in the lateral load resisting walls. Thus, the simulation of seismic response of the walls is the single most significant consideration in the modeling of LWS building analyzed under the seismic design situation.

A simplified diagonal truss model was used to simulate the in-plane force-displacement hysteretic response of the walls. More detail on the modeling of walls can be found in [32]. Pinching4 material [39] is used for the diagonal truss elements. The values of pinching 4 material properties are selected from the studies in the literature [32], in which numerical models of selected wall configurations have been developed.

The development of wall models was followed by the development of 3D building models for the archetypes. The model included only the main structural elements: LFRS walls, gravity load-bearing studs, floor representations, and a P-delta frame. The gravity load resisting studs are modeled as the truss elements. The floor was modeled using the rigid elastic beam-column elements. To capture the lateral displacement arising from the P-delta effect, a rigid frame made of axially rigid elastic beam-column elements with low flexure stiffness having a co-rotational coordinate transformation is connected to the building in the direction of seismic action. Gravity load is applied to the P-delta columns at floor levels. More information on the modeling of CFS archetypes is given in [32]. Moreover, a 2% damping ratio defined based on the Rayleigh damping model is also used in dynamic analysis. These values of damping ratio reflect the values measured during the shake-table tests [32] on LWS building specimens.

## 5.3 Analysis, results, and discussion

To investigate the building performance, pushover analysis and incremental dynamic analysis were performed on the archetypes. The analysis was performed following the framework of the FEMA P695 methodology [33]. More details about the FEMA P695 approach can be found in [32]. Figure 2 show the capacity curves of all archetypes, in which the model base

shear ( $V_b$ ) was normalized by the design base shear ( $F_b$ ) and the design overstrength ( $C/D$  ratio), and the top displacement ( $\Delta$ ) was normalized by building height ( $H$ ).

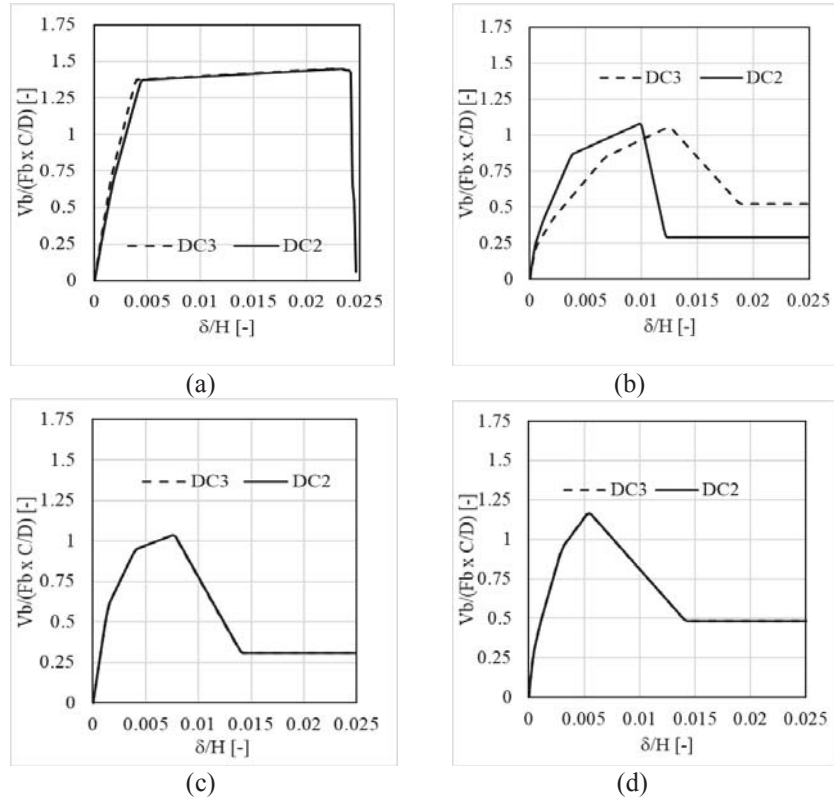

Figure 2: Pushover curves building archetype models braced with: a) CFS strap braced walls; b) CFS shear walls with wood sheathing; c) CFS shear walls with steel sheathing; d) CFS shear walls with gypsum sheathing.

The pushover curves shown in Figure 3 do not highlight any differences among DC2 and DC3 archetypes in terms of building peak strengths, while small differences were observed in the case of building ductility. During the pushover analysis, no brittle failure mechanism was observed. All the archetypes depicted a failure (inter-storey drifts accumulation) at a particular storey.

To better interpret the results, Incremental Dynamic Analysis (IDA) of all archetypes was performed. The analysis was performed using pair of 22 earthquake records provided by FEMA P695 [33]. The collapse performance of archetypes was gauged using Collapse Margin Ratio (CMR). CMR is defined as the ratio between median collapse intensity ( $S_{CT}$ ) to the maximum considered earthquake intensity ( $S_{MT}$ ).  $S_{CT}$  is defined as the intensity at which half of the ground motions in the record set used during the IDA cause collapse of an archetype model. The archetype collapse was represented by the exceedance of the threshold value of an inter-storey drift ratio. The threshold value of inter-storey drift ratio was the level of the drift until which the individual units of lateral load resisting walls did not experience collapse during the tests [32–37–38]. A value of 5%, 2%, and 4% inter-storey drift level was used for archetypes with CFS strap braced, steel sheathed shear, and wood or gypsum sheathed shear wall, respectively.

During IDA, all 44 records (22 records x 2 orthogonal directions) were applied separately to the archetype models in both planar directions. Records were applied in an increment of 20% in their intensity. IDA started with all the earthquake records have an intensity of 20 % (Scaling factor = 0.2) and was continued up to an intensity of 300% or 600% (Scaling factor = 6.0) with increments of 20%, until a failure is not observed. The Scaling factor of 1.0 represents a design

earthquake (DE) level because the median of all the records was matched with the building design response spectrum as explained earlier. The scaling factor of 1.5 can be considered as MCE (Maximum Considered Earthquake) intensity earthquake. This is due to the fact that the MCE is 1.5 times the DE [40]. Figure 3 shows the results of IDA results for the DC2 Class building archetype braced with CFS steel sheathed shear wall.

Figure 3: IDA curves for DC2 class building archetype braced with CFS steel sheathed shear wall.

The CMR obtained from IDA is multiplied with the spectral shape factor (SSF) to obtain Adjusted Collapse Margin Ratio (ACMR). SSF is provided in the FEMA P695 document [33] as a function of period-based ductility ( $\mu_T$ ), numerical fundamental vibration period ( $T_1$ ) and seismic design category of an archetype [41]. FEMA P695 methodology also outlines a performance evaluation process for the archetypes. In particular, it outlines two performance goals: the average value of ACMR,  $ACMR_{avg}$ , for each performance group should be greater than  $ACMR_{10\%}$ , and the individual values of the  $ACMR_i$ , for each archetype should be greater than  $ACMR_{20\%}$ .  $ACMR_{10\%}$  and  $ACMR_{20\%}$  are values of acceptable collapse probability, taken as 10% and 20%, respectively, and are given in Table 7-3 of FEMA P695., which lists them as a function of the total collapse uncertainty  $\beta_{TOT}$ . In this study, the archetypes are not categorized into performance groups due to different lateral force resisting systems, therefore the performance against the second goal  $ACMR_{20\%}$  is only measured.

$\beta_{TOT}$  merges various sources of uncertainty including record to record uncertainty ( $\beta_{RTR}$ ), design requirements uncertainty ( $\beta_{DR}$ ), test data uncertainty ( $\beta_{TD}$ ); and modeling uncertainty ( $\beta_{MDL}$ ) using Equation (8).

$$\beta_{TOT} = \sqrt{\beta_{RTR}^2 + \beta_{DR}^2 + \beta_{TD}^2 + \beta_{MDL}^2} \quad (8)$$

Record to record uncertainty ( $\beta_{RTR}$ ) represents the variability in archetypes response model due to the application of various ground motion records, that could have different dynamic characteristics and frequency content.  $\beta_{RTR}$  is computed using Equation (9).

$$\beta_{RTR} = 0.1 + 0.1 \cdot \mu_T, \text{ with } \beta_{RTR} > 0.2 \text{ and } \beta_{RTR} \leq 0.4 \quad (9)$$

All of the archetypes had  $\beta_{RTR}$  of 0.40. The rest of the parameters in Equation (11) are qualitative indicators provided by FEMA P695 [33] on the basis of the following scale: (a) Superior,  $\beta = 0.10$ ; (b) Good,  $\beta = 0.20$ ; (c) Fair,  $\beta = 0.35$ ; and (d) Poor,  $\beta = 0.50$ . The design process used in this study ensures the formation of ductile mechanism in the walls, while protecting against brittle failure mechanisms happening in wall components. The design method is also able to predict the design strength of the shear wall in a close match to the test results. Therefore, the design requirements used to design the archetypes are rated as “Good” ( $\beta_{DR} = 0.2$ ). In authors opinion, the rating can only be excellent, if the seismic design guidelines for LFRS are

already given in building standards. The available experimental data on LFRS performance is rated as “Superior” ( $\beta_{TD} = 0.1$ ) for CFS shear walls, because different wall components and walls themselves have been tested, [38] and the seismic performance of the building with LFRS has also been investigated via shake-table tests [42]. For strap braced walls, a rating of “Good” ( $\beta_{TD} = 0.2$ ) was utilized because there was no shake table data available on their performance. For DC2 building archetypes braced with the walls, which were obtained by modifying respective DC3 walls, rating of test data was taken as poor ( $\beta_{TD} = 0.5$ ) due to unavailability of test results. Modelling of building archetypes was rated as “Good” ( $\beta_{MDL} = 0.2$ ) due to their ability to simulate brittle failure mechanisms and post peak deterioration of shear strength. Table 5 shows the performance evaluation results of all archetypes.

Archetype		T (sec)	$\mu_T$	S <sub>CT</sub>	S <sub>MT</sub>	SSF	$\beta_{TOT}$	CMR	ACMR	ACMR 20%	ACMR / ACMR 20%
Strap braced	DC2	0.30	13.0	5.40	1.50	1.14	0.70	3.60	4.10	1.80	2.28
	DC3	0.35	13.6	4.20	1.50	1.14	0.50	2.80	3.19	1.56	2.04
Steel Sheathed	DC2	0.28	8.6	2.40	1.50	1.14	0.70	1.60	1.82	1.80	1.01
	DC3	0.31	9.9	1.80	1.50	1.14	0.50	1.20	1.37	1.52	0.90
Wood Sheathed	DC2	0.33	6.0	2.80	1.50	1.12	0.50	1.87	2.09	1.52	1.38
	DC3	0.48	6.4	2.20	1.50	1.12	0.50	1.47	1.65	1.52	1.09
Gypsum Sheathed	DC2	0.29	5.1	2.60	1.50	1.10	0.70	1.73	1.92	1.80	1.07
	DC3	0.30	5.9	2.60	1.50	1.11	0.50	1.73	1.94	1.52	1.28

Table 4 Performance evaluation of building archetypes based on IDA results.

From the results shown in Table 4, it is evident that the proposed design guidelines provide a significant margin of safety (CMR) against collapse. All the archetypes have also ACMR greater than ACMR<sub>20%</sub> except in the case of the DC3 archetype with CFS steel sheathed shear wall.

## 6 CONCLUSIONS

This paper presents the seismic design criteria for LWS buildings. The design criteria cover four different types of LFRS's: CFS strap braced walls, CFS shear walls with steel sheet or wood or gypsum sheathing, which can be used to achieve three levels of ductility classes in LWS building. Special capacity design rules and limitations on the geometrical and mechanical properties are required to be followed for DC2 and DC3 Class structures, while DC1 Class structures require no specific capacity design rules and limitations. Different values of the behavior factors are also proposed for DC2 and DC3 Class structures. Overstrength rules will be provided separately for DC2 and DC3 class structures to safeguard against the brittle failure mechanism in the non-dissipative components. Furthermore, formulations to predict the design strength of the wall would also be provided.

To validate the proposed design criteria, a numerical study was performed considering several building archetypes. Archetypes were designed following the proposed design criteria and modeled in OpenSees. Pushover analysis on archetypes indicated the redundancy of models against the brittle failure mechanism as they were not observed. Through incremental dynamic analysis, the collapse performance of archetypes was evaluated. All of the archetypes passed the FEMA P695 performance evaluation criteria with a good margin except one, in which the performance goal was not met by the close margin. To conclude, based on the numerical results, it can be asserted that the design criteria allow guaranteeing wide margins of safety against collapse and the desired hierarchy of resistances in the LFRS's.

### Abstract

*The behavior of the bolts can strongly influence stiffness, strength, and ductility of joints. The current Eurocodes allows using both HV (German type with failure by nut stripping) and HR (British-French type with failure by necking of the shank) bolts without making any distinction between them. However, recent studies showed that these two types of pre-loadable bolts are characterized by different ultimate tensile behavior that could lead different joint ductility. The aim of this work is to investigate the influence of the type of pre-loadable bolts on the behavior of T-stubs when it is subjected to mode 2 and 3. To this end, analytical and numerical analyses were carried out. The results show that only in case of the failure mode 3 some differences can be observed between HV and HR.*

## 1 INTRODUCTION

The steel structures represent a viable solution in seismic areas providing a very good performance in terms of stiffness resistance and ductility [1-16]. Among them, in the recent years particular attention was given to the bolted connections that are widely used for steel structures due to both their lower constructional costs performance in terms of both resistance and ductility [8-10]. To describe the mechanical characteristics of bolted connections following the code methodology the design relies on the behavior of sub-components. Those representing the end-plate and column flange in bending are analytically modelled with equivalent T-stub connections.

The behavior of T-stubs was widely investigated [17-26] prior to the implementation of the Component method in EN1993-1-8 [1].

The tensile behavior of the bolts plays an important role in the performance of T-stubs. Zhu et al [27] observed two additional failure modes (aside from the three currently considered in [1]) due to nut stripping in the threaded part of the bolt shank. Also D'Aniello et al. [28-29] studied the tensile behavior of European HR and HV preloaded bolts under both monotonic and cyclic loading, showing the significant difference in terms of failure mode and residual resistance. In particular, the failure mode under pure tension of HR bolts is the shank necking, while HV bolts fail under nut stripping with premature loss of strength but larger displacement capacity as respect to the corresponding HR bolts. This aspect may highly affect the T-stub ductility, which can change in function of the type of bolt, while current EN1993-1-8 that allows the indifferent use of both HV or HR bolts.

Therefore, in this paper the influence of the type of preloaded bolts (i.e. either HV or HR) and the effectiveness of the component method in the definition of the T-stub resistance are also experimentally investigated.

The work is organized in four main parts: in the first the design procedure, the experimental setup and the tests results are presented. The second part is focused on the comparison between the experimental results with the analytical model prescribed by the EN1993-1-8.

## 2 DESIGN OF T-STUB SPECIMENS

The geometrical and mechanical features of the T-stub specimens were designed to investigate the behavior under failure mode 2 and failure mode 3 (see Figure 1).

To achieve this purpose the geometry of the specimens was varied on the basis of the relation depicted in Figure 1, which shows that the T-Stub failure modes theoretically vary in function of the ratio  $\beta$  between the tensile resistance of the bolts and sign flexural the strength related to a failure mode 1 of the connected plate ( $4M_{pl,Rd}/m$ ) and the ratio  $\eta$  is the ratio between the T-stub strength ( $F$ ) and the bolt tensile design resistance ( $F_{t,Rd}$ ).

Each region identified in the graph corresponds to the range of features to which one failure mode is associated. As it can be observed, the normalized strength for mode 1 in case of non-circular patterns depends on the ratio  $v = e/m$  (where  $m$  is the distance between the bolt axis and the web of Tee, and  $e$  is the distance between the bolt axis and the plate edge).

**Figure 1** T-stub resistance and corresponding mechanism according to EN1993:1-8

Table 1 summarizes the experimental tests performed on the four specimens varying both the plate thickness and the bolt typologies (i.e. HR or HV). Each specimen is univocally identified by a label code with four parts that is derived from the main feature of the connection, namely:

- the first letter T stands for T-Stub connection;
- the second part identifies the type of preloaded bolt (i.e. HV or HR).
- the last part stands for the thickness of the flange.

The monotonic tensile tests on T-stub specimens were carried out using a universal electro-mechanical MTS testing machine. Tests were carried out under displacement control until failure. To prevent any damage to the test equipment that might have been induced by bolts following their failure, an encasing steel box was mounted on the web of each specimen as shown in Figure 2a and b.

**Figure 2** Description of the experimental setup

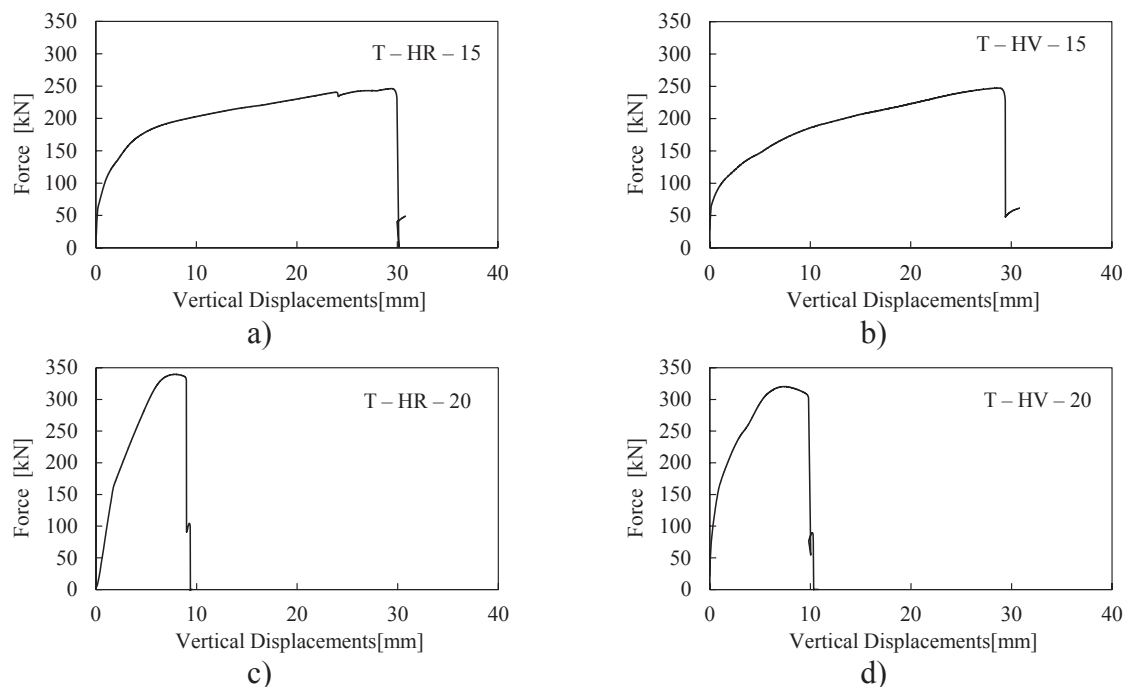

Label [-]	Specimen [-]	Flange thickness $t_f$ [mm]	Bolt type [HR or HV]
T-HR-15	T-15	15	HR
T-HR-20	T-20	20	HR
T-HV-15	T-15	15	HV
T-HV-20	T-20	20	HV

**Table 1** Experimental specimens and relative flange thickness and bolt type

### 3 EXPERIMENTAL TESTS

The experimental results are reported in terms of force-displacement curves (see Figure 3) and in terms of overall failure modes (see Figure 4). In line with the design assumptions, it can be trivially observed that increasing the thickness of the connected plate, the resistance of the specimens increases, and the failure mode moves from the flange to the bolts and ductility decreases accordingly. When a failure mode 2 is observed (e.g. see T-S-HV/HR-15), the plastic deformations are balance between the flange and the bolts; in these cases indeed large plastic deformations can be observed in the plates (see Figure 4 a and b) and in the bolts independently from the their typologies (i.e. HR or HV). The test was stopped only at very large displacements, where the fracture in the bolts was observed (see Figure 4 a and b); it is important to observe that in both the investigated cases, all the bolts show the same failure mode due to a fracture in the shank.

Indeed, when large displacements are reached a membrane action develops in the flange, thus the bolts are not subjected only to the tensile action but also to shear. This mechanism is clearly observable in the specimens T-S-HR/HV-15, where the ovalization of bolt-holes is shown in Figure 4 a and b.

**Figure 3** T-stub results in terms of force displacement curve

Contrariwise, increasing the flange thickness imply a larger demand in the bolts that are mainly subjected to the tensile action without developing significant prying forces. In these cases,

despite no appreciable differences can be observed in terms of force displacements curve, the failure of the two family of bolts is different and it is function of their typologies.

**Figure 4** Failure mode and bolts rupture of the investigated T-Stub

#### 4 CONCLUSIONS

The influence of the type of preloaded high-strength bolts on the T-stub behaviour were investigated by means of four experimental tests.

Although the tensile failure modes of HV and HR bolts are significantly different (i.e. nut stripping and shank necking, respectively), the experimental tests showed that the mode 2 response of T-Stub connections is not affected by the different types of preloaded bolts. This result is mainly due to the type of failure exhibited by bolts that is never under pure tension, but it occurs for a combination of bending moment, axial force and shear force. Hence, HV and HR bolts can be used without any distinction when T-Stub connections are designed to experience mode 1 and 2.

Of course, in the case of very thick flange (i.e. when the resistance of mode 3 is about 3 times or more the resistance of mode 1) the different types of tensile failure mode of the bolts influence the residual resistance of the connection.

### Abstract

*The orthogonal exoskeletons can be used in seismic application to retrofit an existing building without interfere with the structure operativity. These types of structures are usually placed on the external perimeter of the existing structures and contribute to absorb the horizontal action in case of seismic events. The exoskeletons should be designed in function of the design target and depending on the lateral stiffness of the existing structures. Therefore, the exoskeletons lateral stiffness represents one of the key parameters in the design procedure; however, their structural stiffness is influenced by the joint features. In this work, the influence of the geometrical and mechanical characteristics of the joint on the global exoskeleton's performance is investigated. Non-linear numerical analyses were performed in order to investigate the performance of the exoskeletons accounting for the presence of the joints by the introduction of a no-dimensional local spring. The results show that the local response of the exoskeletons is affected by the joints features, and that in the design phase it is important to take into account the real exoskeletons lateral stiffness.*

---

## 1 INTRODUCTION

Exoskeletons are shear walls composed by steel members. Such kind of resisting systems can be located on the perimeter of an existing building to increasing its lateral stiffness, thus improving the seismic response of the structure [1-5]. Exoskeletons can exhibit a 3-dimensional or 2-dimensional lateral behaviour; with reference to 2-D systems, a further distinction can be made between parallel and orthogonal exoskeletons, in dependence from their orientation with respect to the existing building facades. The present work concerns with 2-D orthogonal exoskeletons (EXO-2D- $\perp$ ), which can represent a competitive strategy for the seismic retrofit of existing structures; indeed, no interruption of productive activities within the building is required for the installation of these systems, which are also suitable for serial production.

Exoskeletons design is mainly governed by the global analysis of the existing structure in presence of lateral loads. However, a considerable influence on the actual structural behaviour is also played by geometrical and mechanical features of the joints, which can modify the whole exoskeleton lateral stiffness in dependence from their local flexural response.

Therefore, in the present paper the influence of joint detailing on the global exoskeleton performance is investigated by means of non-linear numerical analyses. For this purpose an existing reinforced concrete school building located in Italy has been selected as case study.

This work is divided in three parts. In the first section the description of the investigated structure is presented, paying particular attention to its structural deficiencies; the main features of adopted exoskeletons and the different configurations investigated for the relative joints are described in the second part. Finally results of non-linear numerical analyses are presented and commented in the last section.

## 2 DESCRIPTION OF THE CASE STUDY

The selected structure, which is located in province of Macerata, was realized during 1965 to serve as a school building. In analogy with other constructions built in the same period in Italy, the resisting structure has been made using reinforced concrete (RC) and designed only to withstand gravity loads, neglecting any seismic action. The building is articulated on three levels (with a total height of 10.9 m) and has an almost squared footprint of 22 x 17.9 m<sup>2</sup>.

In Figure 1 are depicted an overall view of the case study and its relative building plan.

It can be noticed that RC moment resisting frames are basically unidirectional; indeed, while four main frames are disposed along X direction, only two frames are arranged along the Y direction to act as edge closures, although the presence of a pair of concrete shear walls oriented in the vertical direction (functioning as stairwell) has to be remarked.

Figure 1: Overall view of the selected school building (a) and relative building plan (b)

A preliminary analysis of the structure has been carried out by the Authors to highlight its critical structural deficiencies, which can be summarized as follows:

- The lack of RC moment resisting frames in the vertical direction, which is a direct consequence of a non-seismic structural conception, leads to the absence of a 2-dimensional structural grid which is necessary to resist seismic actions;
- Both beams and columns are characterized by a large spacing among the steel stirrups, exposing the members to fragile shear mechanisms and reducing the confinement efficiency;
- Since the first two floors are partially underground, inter-story height is inhomogeneous, thus the structure cannot be considered regular along its elevation;
- Testing of materials showed that concrete has poor mechanical characteristics (i.e. its mean compressive strength is lower than 10 N/mm<sup>2</sup>).

### 3 DESCRIPTION OF EXOSKELETONS AND JOINTS

#### 3.1 Description of adopted exoskeletons

The structural criticalities which emerged from the preliminary analysis of the case study made EXO-2D- $\perp$  a viable strategy for the seismic retrofit of the building. Exoskeletons have been designed in accordance to Italian seismic provisions currently in force to allow the structure to resist the full seismic demand expected in the edification site (PGA = 0.202 g for life-safety limit state, considering a service life equal to 75 years), thus restoring a seismic safety factor IS-V equal to 1.

Moreover, although in general exoskeletons can be designed as dissipative systems, in this application EXO-2D- $\perp$  have been proportioned in order to always remain in their elastic range. Among the different possible configurations, a tapered Y-shaped concentrically braced (CBF) solution (see Figure 2a) has been chosen in order to maximize the lateral stiffness incrementation without obstructing the passage in correspondence of the steel frames.

As depicted in Figure 2b, orthogonal exoskeletons have been placed in correspondence of all existing RC frames and nearby the concrete shear walls. Therefore, in order to minimize eccentricity between centre of mass and centre of stiffness two additional systems have been placed in the Y direction on the lower facade.

S355 Circular hollow sections (CHS) have been used for all steel members. The designed cross-sections of all different structural elements (i.e. chords, vertical struts and diagonals) are reported in Table 1.

Figure 2: Morphology of adopted orthogonal exoskeletons (a) and relative disposition in plan (b)

Structural member	Diameter [mm]	Thickness [mm]
Chords	244.5	12.5
Vertical Struts	177.8	12.0
Diagonals	139.7	10.0

Table 1: Geometrical features of designed structural members.

### 3.2 Description of investigated joint configurations

Figure 3 depicts the different kinds of considered joint configurations. According to EN1993:1-8 (EC3-1-8), the three investigated alternatives can be identified as rigid (Fig. 3a), semirigid (Fig 3b) and nominally pinned joint (Fig. 3c), respectively. Pinned configuration is made with bolted pins connected to a gusset plate which is in turn fillet-welded to the vertical strut, which subsequently is the only structural member preserving its flexural continuity. In case of semirigid joints all steel members are directly connected to each other by means of fillet welds. To fulfil the EC3-1-8 requirements for a rigid joint the addition of stiffening plates was needed. The effect of local flexural stiffness of the joints has been investigated using SAP2000 v.21 by means of non-dimensional and non-linear spring elements. Constitutive parameters of these elements have been evaluated by means of preliminary finite element analyses. Plasticization in RC elements has been simulated introducing concentrated plastic hinges modelled in accordance with ASCE 41-13 provisions (see Figure 4).

## 4 RESULTS OF NUMERICAL ANALYSES

In order to investigate the influence of joint detailing on the global response of designed EXO-2D- $\perp$ , a total of 24 non-linear static analyses (Pushover) have been conducted on both a singular exoskeleton and on the whole retrofitted structure.

Figure 3: Representation of investigated joint configurations: rigid joint (a), semirigid joint (b) and nominally pinned joint (c).

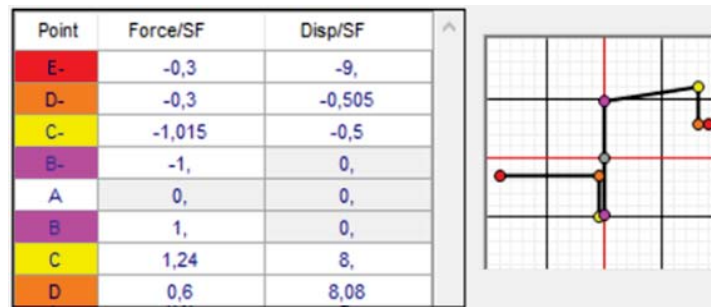

Figure 4: Constitutive relation adopted for plastic hinges.

Figure 5: Structural scheme of a single exoskeleton implemented in SAP2000 v. 21

Both modal and mass proportional force distributions were considered; the seismic actions was applied on both the principal directions of the building. The structural scheme of an exoskeleton as implemented in SAP2000 v.21 is depicted in Figure 5.

Pushover curves for a single EXO-2D- $\perp$ , which are reported in Figure 6, display the influence of joints flexural stiffness on the global response of the system. Indeed, the structural behavior is slightly different when pinned joints are used in place of rigid or semirigid connections. This difference is most noticeable if the exoskeleton is subjected to tension; indeed, after the first yielding the pinned solution displays a more ductile behavior accompanied by a lower value of base shear force. No significant variation can be appreciated while the exoskeleton is in its elastic range. This evidence also explains the almost equivalent behavior of EXO-2D- $\perp$  in compression for all different joints configurations, since in this case the collapse mechanism is governed by global buckling of the first floor diagonal, which causes a sudden loss of capacity without any plasticization phenomenon. Figure 7 reports pushover analyses for the whole retrofitted structure in function of the adopted joints configuration.

(a)

Figure 6: Pushover curves for a single exoskeleton in case of modal (a) and mass (b) force distributions.

Figure 6: Pushover curves for the retrofitted structure in case of modal distribution forces applied along the X direction (a) and Y direction (b).

One can notice that all investigated solutions display almost the same global response. This outcome is consistent with results relative to a single EXO-2D-⊥.

Indeed, while the influence of joint detailing becomes appreciable in the post-elastic range, it should be remarked that the proposed exoskeletons were all designed to always behave elastically. Moreover, these kind of exoskeletons are prevalently subjected to an axial regime, thus reducing the importance of flexural stiffness on their overall response. Nevertheless, X direction pushover analyses display a more ductile global behavior with respect to Y direction ones. This outcome depends from the disposition of resisting RC systems in the existing structures. Indeed, since all EXO-2D-⊥ remain elastic, the plasticization is concentrated in the RC beams ends, which are almost absent along the Y direction. Therefore, in the vertical direction the structural performance is highly influenced by exoskeletons response, resulting in a more brittle behavior.

## 5 CONCLUSIONS

The influence of joint detailing on the global behavior of 2-D orthogonal exoskeletons has been investigated by means of non-linear numerical analyses. For this purpose an existing school building located in Italy has been selected as case study. From analyses results the following conclusions can be pointed out:

- The influence of joint flexural stiffness on EXO-2D- $\perp$  global behavior is most noticeable in the post-elastic range;
- In post-elastic range pinned solutions display a more ductile behavior with a lower base shear with respect to semirigid or rigid configurations;
- Since the retrofitting of the case study involved exoskeletons designed to remain in their elastic range, there is a minimum difference among the considered solutions;
- Further studies will be conducted considering dissipative exoskeletons to investigate more widely the influence of joint flexural behavior on the structural response when EXO-2D- $\perp$  are in the post-elastic range.

### Abstract

*Many typical historical masonry churches, with one nave and wooden roofs, have shown high seismic vulnerability in the recent seismic events, especially under transverse earthquakes. In fact, the nave transverse response of this kind of constructions is influenced both by the materials features and the geometrical characteristics. In order to improve the seismic response, the box behavior strategy basing on dissipative roof-diaphragm, can be pursued by adopting cross laminated timber panels (CLT). In this paper, for five historical masonry churches, the effectiveness of different CLT panels solutions is investigated by performing comparative non-linear dynamic analyses adopting equivalent finite element models. The CLT solutions differ themselves for the panels thickness (6mm and 10mm) and the number of the connections (8, 16 and 32 crews in one linear meter). The results are shown in terms of dimensionless transverse displacement (drift) and shear occurred at the base of the façade. Therefore, the influence of the most important geometrical features (as slenderness of the perimeter walls, the width and the length of the churches) in the seismic response is pointed out for each church equipped by different CLT roof-diaphragm solutions.*

**Keywords:** Historical Churches, Seismic Vulnerability, Roof-Diaphragm, Time-History analysis.

## 1 INTRODUCTION

In the historical masonry churches the observation of post-earthquake damages allowed the identification of several recurring collapse mechanisms [1, 2, 3]. In the nave transversal response [4] an excessive rocking of the perimeter walls can lead to: (i) out-of-plane mechanisms with a consequent collapse of the roof structure supports [5, 6, 7] or (ii) in-plane excessive stress in the walls in parallel located with respect to the earthquake. On the other hand, the historical masonry churches with wooden roof structures, realized in several configurations in according to the traditional construction techniques of the location site [8, 9], were originally designed to withstand static loads even if the constructions are in regions nowadays classified as seismic [10-15]. To preserve the cultural heritage, the seismic strengthening of historical churches represents a mandatory issue achieving by retrofitting strategies able to provide the “global box behavior” to the construction. Therefore, after accurate analyses about (i) the conservation status of the masonry and wooden elements, (ii) the clamping between the head and perimeter walls and (iii) the wall-to-roof connections, the retrofitting operations can be chosen in order to avoid both out-of-plane and in-plane collapse mechanisms.

Comparative analyses among churches with same configuration can be useful to predict the structural failure in seismic response and to orient the retrofitting techniques [16-20] according to the conservative restoration criteria satisfying, as far as possible, the original material compatibility without changing the authenticity of the constructions [21, 22, 23]. Among these techniques the realization of dissipative wooden based roof-diaphragm represents a valid option because the out-of-plane rocking of the longitudinal walls can be reduced limiting the in-plane shear actions transferred to the head walls [24]. Several wooden based roof-diaphragm configurations can be realized [25, 26, 27]. One of these is based on the use of Cross Laminated Timber (CLT) panels characterized by an alternated sequence of glued timber layers [28, 29, 30]. This kind of panels have been initially adopted in new timber buildings [31-34] but, in several experimental tests and numerical analyses, they have shown enough in-plane stiffness able to guarantee the floor diaphragm effect especially if the panels are over-placed on the existing wooden beams or planks creating wood-to-wood composite sections [35, 36, 37]. Under the seismic actions, the energy dissipation in the timber roof-diaphragm must be occurred in the panel-to-panel and wall-to-panel connections, as a consequence the roof diaphragm should be designed in terms of strength, stiffness and ductility [13, 38]. In fact, if the connection resistance exceeding the seismic demand an elastic response without energy dissipation can be occurred, vice versa an excessive stiffness can increase the shear in the folded CLT panels with a consequent thickness increase.

Considering the previous issues, the present work is aimed to evaluate the influence of the geometrical and material features on the nave transverse response for different one nave configuration churches, reinforced by CLT roof structures, under the same seismic action. An adequate representation of the non-linear behavior of the masonry and roof-diaphragm (CLT panels with steel connections) is required to investigate the seismic response under the transverse earthquake [19, 39, 40]. In this way, several methods with different level of accuracy and computational costs should be considered [41], e.g. simplified method [42], limit analysis [43], macro-modelling based on finite element method [44] and equivalent models [25]. These methods are generally based on the discretization of the structure by macro-elements, with concentrated non-linear properties. In the present work, the macro-elements approach is used by equivalent models implementation with vertical mono-dimensional elements representing the masonry elements and horizontal ones representing the roof diaphragm [45]. Non-linear dynamic analyses are performed by introducing the seismic action as time histories in order to simulate the damped rocking mechanism pursued by the dissipative roof-diaphragm.

## 2 EQUIVALENT MODEL

The non-linear dynamic analyses have been performed considering an equivalent finite element model where the structural elements involved in the seismic response of the church are schematized with mono-dimensional macro-elements. In fact, the church was subdivided into  $n$ -seismic resistant systems transversally disposed with respect to the nave: façade, lateral walls coupled themselves, triumphal arches and head wall (Figure 1). The non-linear properties of the perimeter masonry walls and the CLT roof diaphragm are assigned to the related equivalent elements according to [25].

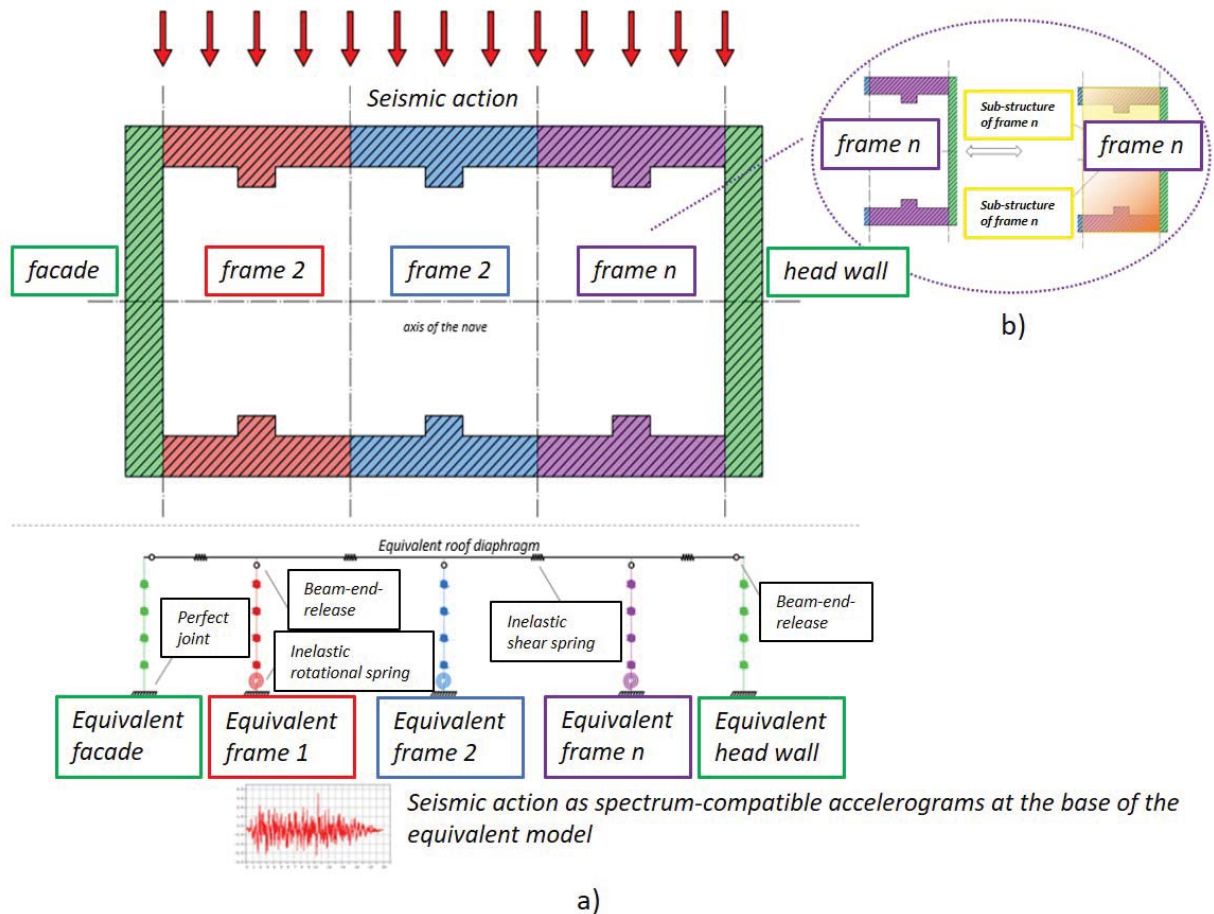

Figure 1: a) Identification of seismic resistant frame in the one nave configuration church (plan view) and related equivalent finite element model representation (longitudinal view) and b) plan view of the sub-structures characterizing the  $n$ -seismic resistant frame.

To implement the equivalent finite element model, three main steps are considered. In the first step, pushover analyses are performed considering the sub-structures schematizing the single parts of the  $n$ -seismic resistant systems as the piers of the longitudinal walls included within the openings or the abutments (Figure 1 and 2a). Each sub-structure is subdivided in section with fibers discretization where the non-linear characteristics are calculated considering a trilinear constitutive law with tensile strength equal to 0 or concrete damaged elasticity model [46, 47] in which tensile cracking and compressive crushing as main failure modes.

In the second step, the yielding and ultimate values obtained by the  $M$ - $\chi$  diagrams calculated through the pushover analyses performed in the first step, are used to implement the inelastic rotational springs assigned at the base of the seismic resistant elements considering a bi-linear constitutive law. Pushover analyses are again carried out in order to obtain the base

shear-top displacement ( $V-\delta$ ) curves of the transversal resistant system and the  $M-\chi$  which characterizes each system is evaluated considering the related shear length (Figure 2b).

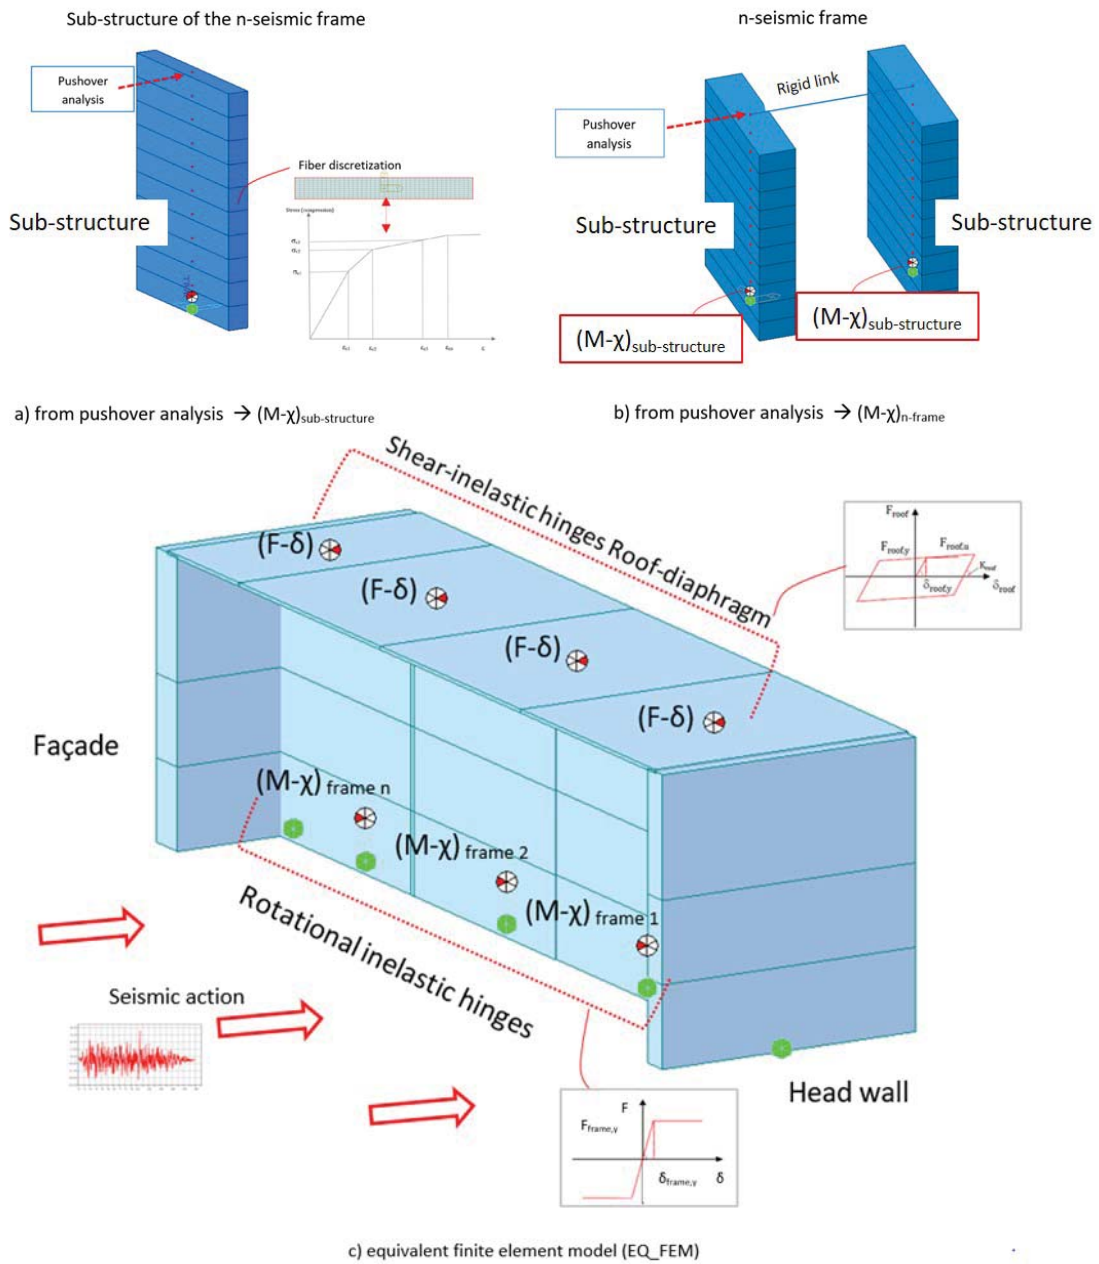

Figure 2: a) pushover analyses on sub-structures, b) pushover analyses on seismic resistant frame with inelastic rotational springs having  $M-\chi$  detected in step a) and c) equivalent finite element model under seven spectrum-compatible accelerograms.

In the third step, the head wall, the façade and the transversal frames are schematized through mono-dimensional equivalent elements. Furthermore, the façade and the head wall are implemented by equivalent elastic mono-dimensional elements fully restrained at the base, considering that their in-plane strength and stiffness are greater than the longitudinal walls [25, 48]. The transversal frames are characterized by the presence of concentrated inelastic rotational springs located at the base and obtained from the above-mentioned  $M-\chi$  diagrams calculated during the second step (Figure 2c). The equivalent finite element model (EQ\_FEM) is

completed through the application of horizontal mono-dimensional equivalent elements representing the roof-diaphragm. The elements of the roof are linked to the vertical ones by hinges located at the end of the vertical elements in order to trigger the rocking and it allows to not transfer the bending moment to the roof. The equivalent elements of the roof are also pinned with respect to the head wall and façade. The shear deformability that characterizes the roof and the non-linear behavior of the connections are implemented to consider the dissipative response of the roof diaphragm through elasto-plastic shear hinges. The shear roof springs are implemented considering a trilinear degrading model [49] or Clough model [28, 50, 51] where the unloading stiffness is calculated considering the reduction of the elastic one with the following relation:

$$K_R = K_0 |D_y / D_m|^\alpha \leq K_0 \quad (1)$$

where  $K_R$  is the unloading stiffness,  $K_0$  is the elastic stiffness,  $D_y$  is the yield displacement,  $D_m$  is the maximum displacement and  $\alpha$  is the unloading stiffness degradation parameter, in this case equal to 0.4. The unloading stiffness gradually reduces when the deformation increases. The seismic action is applied considering a set of spectrum-compatible accelerograms acting transversely to the nave.

### 3 DAMPED ROCKING RESPONSE

The CLT panels, the wall-to-roof and wall-to-wall connections represent a deformable diaphragm which allow the rocking trigger of the perimeter walls but limiting either the drift in a fixed design range and the seismic loads on the rigid head walls (thanks to the energy dissipation occurred in the steel connections). The dissipative roof-diaphragm represents a damper located at the top of the constructions with a behavior analogous to one of a top located damper [4]. By the dissipative roof-diaphragm, the nave transverse response of one nave historical church, usually characterized by high percentage of the total mass involved in the first vibrational mode, can be represented by flag-shaped diagram (Figure 3c) obtained from the bi-linear free rocking behavior of the masonry seismic resistant systems (Figure 3a) [45] and the (ii) the dissipative hysteretic behavior of the roof-diaphragm (Figure 3b) [52, 53].

It is possible to represent the bi-linear behavior of the free rocking through the yielding ( $F_{frame,y}$ ) and ultimate ( $F_{frame,u}$ ) force related to the yielding ( $\delta_{frame,y}$ ) and ultimate ( $\delta_{frame,u}$ ) displacement of the generic resistant seismic frame, obtained by the pushover analyses performed during the second step and mentioned in Section 2. The frame stiffness is calculated considering the following relation:

$$k_{frame} = F_{frame,y} / \delta_{frame,y} \quad (2)$$

Furthermore, it is possible to schematize the dissipative behavior of the roof considering the yielding ( $F_{roof,y}$ ) and ultimate ( $F_{roof,u}$ ) force related to the yielding ( $\delta_{roof,y}$ ) and ultimate ( $\delta_{roof,u}$ ) displacement that characterizes the roof. These values are obtained by the experimental tests on the connector chosen for the connections [28, 54]. Similarly, the roof stiffness is evaluated as follow:

$$k_{frame} = F_{roof,y} / \delta_{roof,y} \quad (3)$$

The flag shaped diagram, shown in Figure 3c, is based on two fundamental hysteretic variables  $\zeta$  and  $\beta$ , defined as follow:

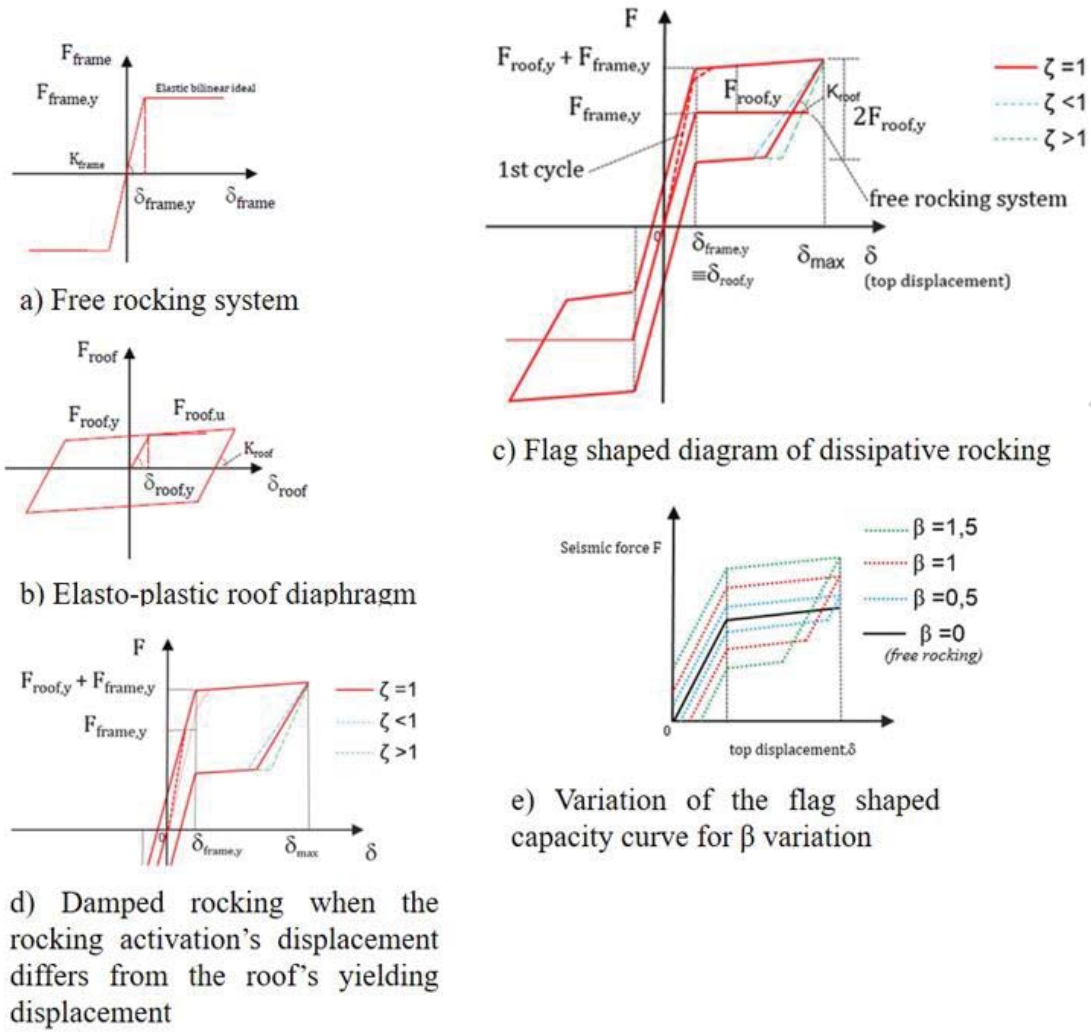

Figure 3: damped rocking diagram.

$$\zeta = (F_{\text{roof},y} \cdot k_{\text{frame}}) / (k_{\text{roof}} \cdot F_{\text{frame},u}) \quad (4)$$

$$\beta = 2 F_{\text{roof},y} / F_{\text{frame},y} \quad (5)$$

It is possible to define the yielding force of the roof in terms of  $\beta$ :

$$F_{\text{roof},y} = (F_{\text{frame},y} \cdot \beta) / 2 \quad (6)$$

while the roof stiffness can be calculated considering both  $\zeta$  and  $\beta$  parameters:

$$k_{\text{roof},y} = (k_{\text{frame}} \cdot F_{\text{roof},y}) / (\zeta \cdot F_{\text{frame},y}) \quad (7)$$

$$k_{\text{roof},y} = k_{\text{frame},y} \cdot [(\beta \cdot \delta_{\text{frame},y}) / (2 \cdot \delta_{\text{roof},y})] \quad (8)$$

It possible to notice that  $\zeta$  can be described through the ratio between the yielding displacement of the roof and the yielding displacements of the frame ( $\zeta = \delta_{\text{roof-y}} / \delta_{\text{frame-y}}$ ) and pro-

vides a measure of the roof diaphragm. As shown in Figure 3d,  $\zeta$  is indirectly proportional to  $k_{\text{roof}}$  because if  $\zeta$  increases, lower energy dissipation occurs.

The  $\beta$  parameter is fundamental for the correct intervention design because it is an index of the energy dissipated by the roof: if  $\beta$  increases, the damping effect increases (Figure 3e). Usually, the  $\beta$  value is between 0 and 1.5. In fact,  $\beta < 2$  is preferable because it allows the self-centering rocking behavior whereas for  $\beta > 2$  there-centering functioning is partially inhibited having a flag-shaped diagram with significant residual displacement, as shown in Figure 3e where the diagram changes from blue line to green one.

The roof diaphragm stiffness, related to the wood elements and the steel connections, is evaluated considering the bending stiffness  $k_{\text{df}}$  and the shear stiffness  $k_{\text{dt}}$ :

$$k_{\text{roof}} = (1/k_{\text{df}} - 1/k_{\text{dt}})^{-1} = [(5/6) \cdot (L^3/E_w^* \cdot J_{\text{id}}) \cdot (\chi L/G_w^* A^*)]^{-1} \quad (9)$$

where  $E_w^*$  is the equivalent elastic modulus,  $G_w^*$  is the equivalent shear modulus and  $J_{\text{id}}$  is the ideal inertia moment of the section:

$$E_w^* = [(Lk_n/n_s)/(2 \cdot ((t_w L_y / \cos \alpha)/n_n) + ((k_n(L/n_s))/E_w))] \quad (10)$$

$$G_w^*(n_n, n_s) = [(Lk_n/n_s)/(2 \cdot ((t_w L_y / \cos \alpha)/n_n) + ((k_n(L/n_s))/G_w))] \quad (11)$$

$$J_{\text{id}}(n_n, n_s) = (t_w L^3 / 12 \cos \alpha) + n_{\text{ws}} \cdot [2A_s (L_y/2)^2] \quad (12)$$

considering that  $n_{\text{ws}}$  is the homogenization coefficient of the steel connection to the wooden diaphragm ( $n_{\text{ws}} = E_s/E_w^*$  where  $E_s$  is the Young modulus of the steel),  $L$  is the distance between the transversal seismic resistant elements and the central nave,  $L_y$  is the roof width,  $k_n$  is the stiffness of the single connector,  $t_w$  is the panels thickness,  $n_s$  is the number of the connections stripes for each span,  $n_n$  is the number of connectors for each connections stripe equal to the ratio between the inter-axis of the seismic elements and the inter-axis of the connectors.

The initial value of  $k_{\text{roof}}$  depends on the geometrical characteristics and the material properties of the CLT panels and on the connections details, calculated according to [24, 25]. This value of  $k_{\text{roof}}$  can be used in the non-linear dynamic analyses even if the optimum roof stiffness ( $k_{\text{roof-opt}}$ ) could be consequently evaluated in correspondence to optimal  $\beta$  ( $\beta_{\text{opt}}$ ) able to limit the drift under the design value  $\delta_{\text{design}} \leq 0.005h_w$ , where  $h_w$  is the height of the perimeter walls [25].  $k_{\text{roof-opt}}$  is evaluated according to the following relation:

$$k_{\text{roof-opt}} = (\beta_{\text{opt}} \cdot k_{\text{frame}})/2\Delta \quad (13)$$

where  $\Delta$  is the ratio between the yielding displacement ( $\delta_{\text{roof,y}}$ ) of the roof and the yielding displacement of the frame ( $\delta_{\text{frame,y}}$ ). The approach is valid because the drift limitation is the first step towards the evaluation of the roof-diaphragm effectiveness. Furthermore, the stiffness of the roof-diaphragm does not influence the intensity of the seismic action on the structure, vice-versa it affects the maximum drift.

## 4 CASE STUDIES

The parametric non-linear dynamic analysis is carried out considering some of the fundamental geometrical features that characterize the five existing one nave historical churches under study (Figure 4) strengthened by four different CLT panels roof structure configurations,

varying the value of  $\beta$  between 0.1 and 1.5. Table 1 shows the values of the geometrical and material characteristics of the above-mentioned churches under study, where  $C$  is the number of spans,  $l_c$  is the length of the church,  $l_f$  is the width of the church,  $t_w$  is the average thickness of the lateral walls,  $h_w$  is the height of the lateral walls,  $\lambda_w$  is the geometrical slenderness of the walls given by the ratio  $\lambda_w = h_w / t_w$ ,  $h_f$  is the height of the façade,  $\lambda_f$  is the geometrical slenderness of the façade given by the ratio  $\lambda_f = h_f / l_f$ ,  $S_F$  is the shape factor ( $S_F = l_c / l_f$ ),  $E_m$  is the elastic modulus of the masonry,  $G_m$  is the shear modulus of the masonry and  $w_m$  is the weight density of the masonry while Figure 5 reports the value of the geometrical characteristics of the churches.

## 5 RESULTS

The results of the parametric analysis, considering a  $\beta$  value ranging between 0.1 and 1.5, are discussed in terms of two parameters: (i) the ratio between the drift and the height of the lateral walls (dimensionless drift) and (ii) the ratio between the base shear and the axial force on the same equivalent element (dimensionless base shear) taking into account the geometrical slenderness of the walls ( $\lambda_w = h_w/t_w$ ), the geometrical slenderness of the façade ( $\lambda_f = h_f/t_f$ ) and the shape factor ( $S_F = l_c/l_f$ ).

The drift, the base shear and the axial force are evaluated, considering the results obtained by the equivalent element models, as the average values of the maximum ones under the seven spectrum-compatible accelerograms.

The first step of the parametric analysis regards the choice of the optimum  $\beta$  value for each church under study, considering the different roof diaphragm configurations. Figure 7 shows the results obtained from the numerical analyses where the design drift is taken equal to 5% of the height of the lateral walls (green line).

Figure 7: dimensionless drift –  $\beta$  trend.

It is possible to notice that the drift decreases for high values of  $\beta$  parameter because a higher energy dissipation occurs in the connections, according to as reports in Figure 3. Furthermore, the panels thickness influences the seismic response. In fact, considering the same church, when the thickness panels increases the target drift is achieved for lower value of  $\beta$ .

Another important aspect regards the percentage variation of the dimensionless drift ( $\Delta\eta$ ) for each church and the four roof diaphragm configurations by varying  $\beta$  with respect to the single plank roof-configuration (taken as zero condition). Figure 8 shows the  $\Delta\eta$ - $\beta$  trend evaluated for each church under study which are useful to understand the drift improvements as a function of  $\beta$ . It is possible to notice that considering the same church, the variations are more evident for panels with higher thickness. Furthermore, for the same panels thickness, the number of connections slightly influences the variations.

The third consideration regards the variations of the dimensionless base shear of the central equivalent elements and the dimensionless base shear of the façade (Figures 9 and 10). In this case, the results show that the dimensionless shear variations for the central equivalent element and for the façade are in opposite themselves. When  $\beta$  increases, the base shear of the central equivalent element decreases considering that this seismic resistant element is located in the area in which the top displacement is maximum. Consequently, in the central part of the church, the drift and the base shear are in opposite themselves. Similar consideration can be made for the façade. Considering the thickness panels of the roof diaphragm, when this increases the base shear of the central equivalent element decreases. On the contrary, the façade base shear is lower for minor thickness panels.

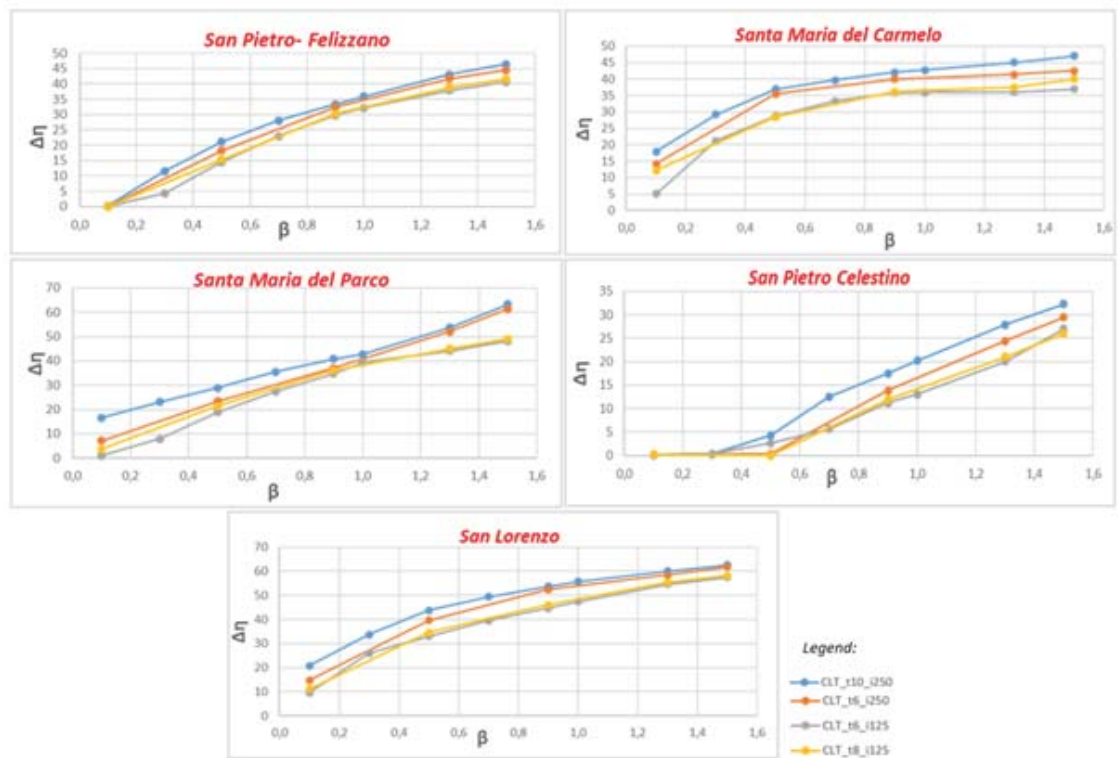

Figure 8:  $\Delta\eta$ - $\beta$  trend.

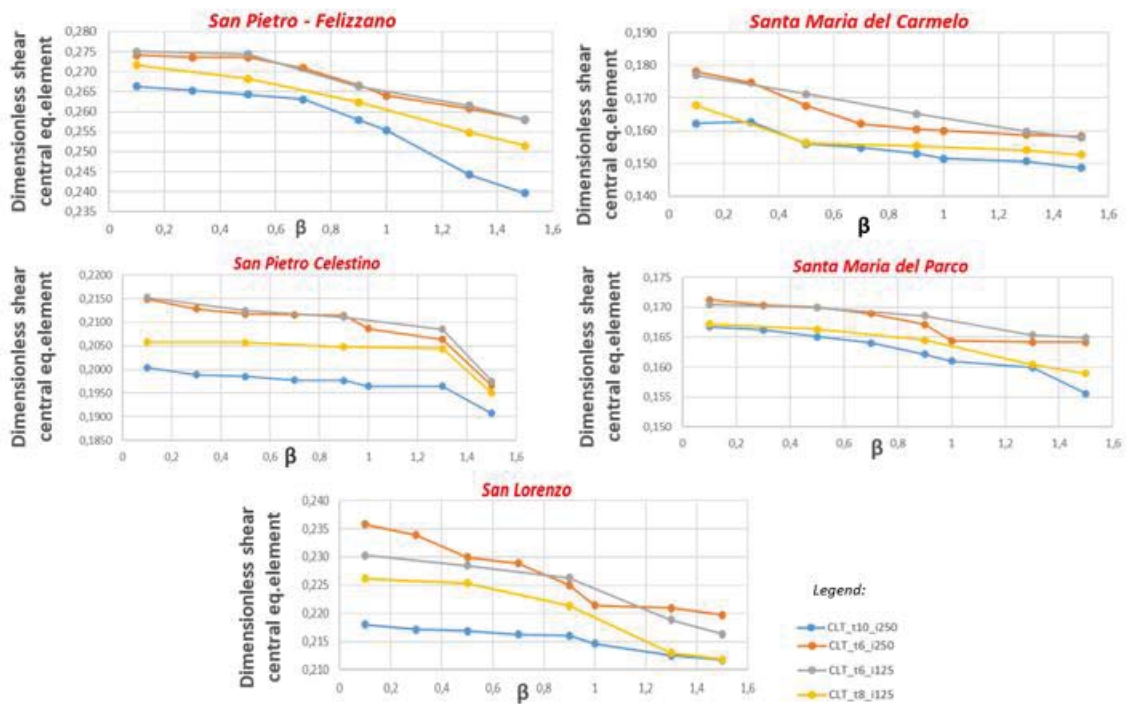

Figure 9: variation of the dimensionless base shear for the central equivalent element as a function of  $\beta$ .

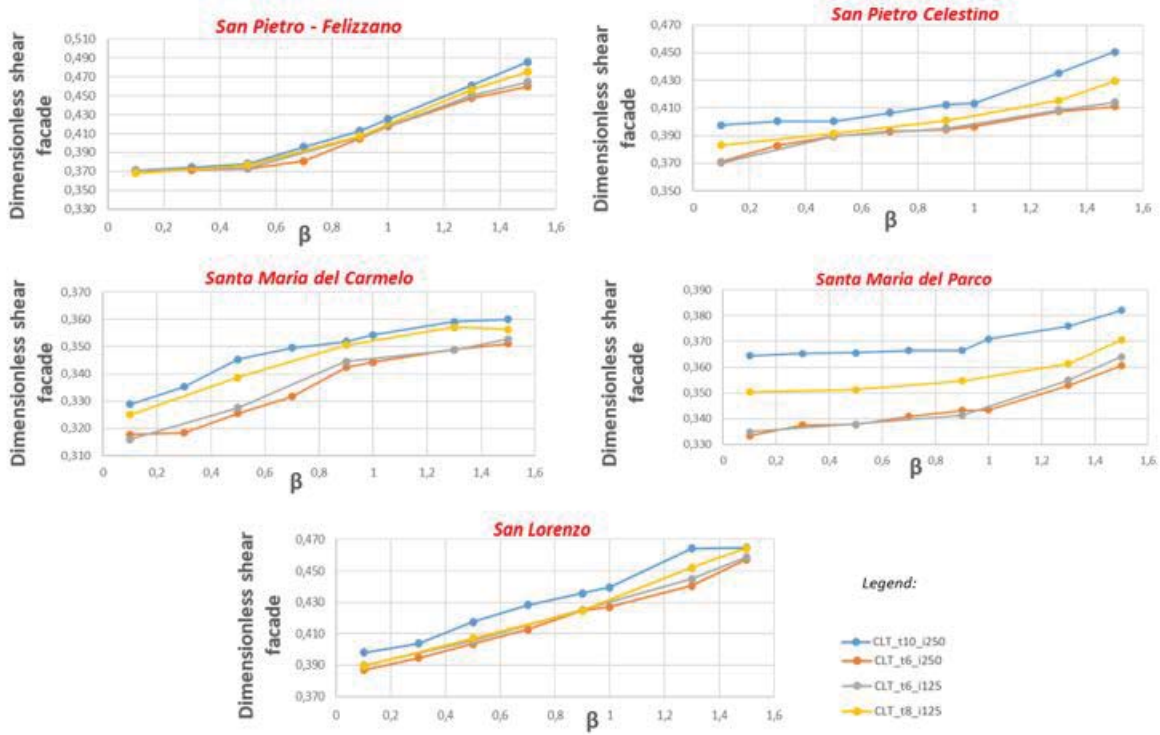

Figure 10: variation of the dimensionless base shear for the façade as a function of  $\beta$ .

The influence of the geometrical slenderness of the walls ( $\lambda_w$ ) and the façade ( $\lambda_f$ ) on the seismic response of the churches under study are analyzed considering the different roof diaphragm configurations. Figures 11 and 12 summarize the results obtained by the numerical analyses.

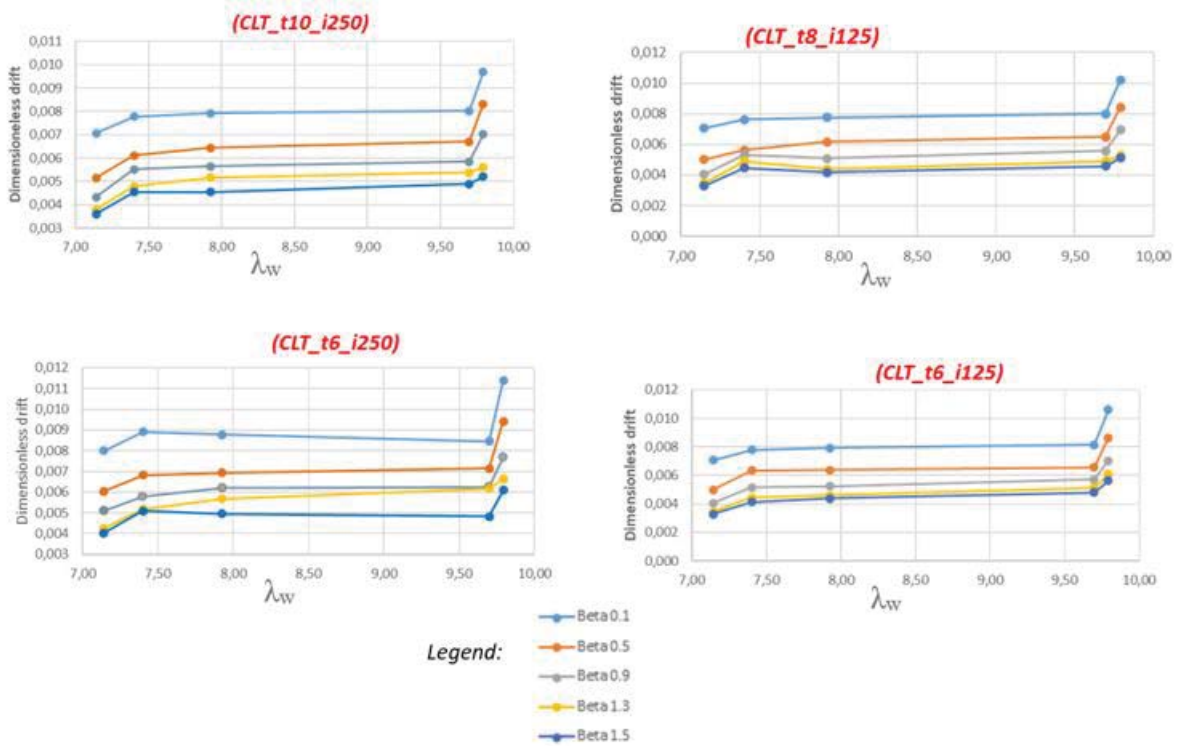

Figure 11: dimensionless drift in comparison to the geometrical slenderness of the lateral walls ( $\lambda_w$ ).

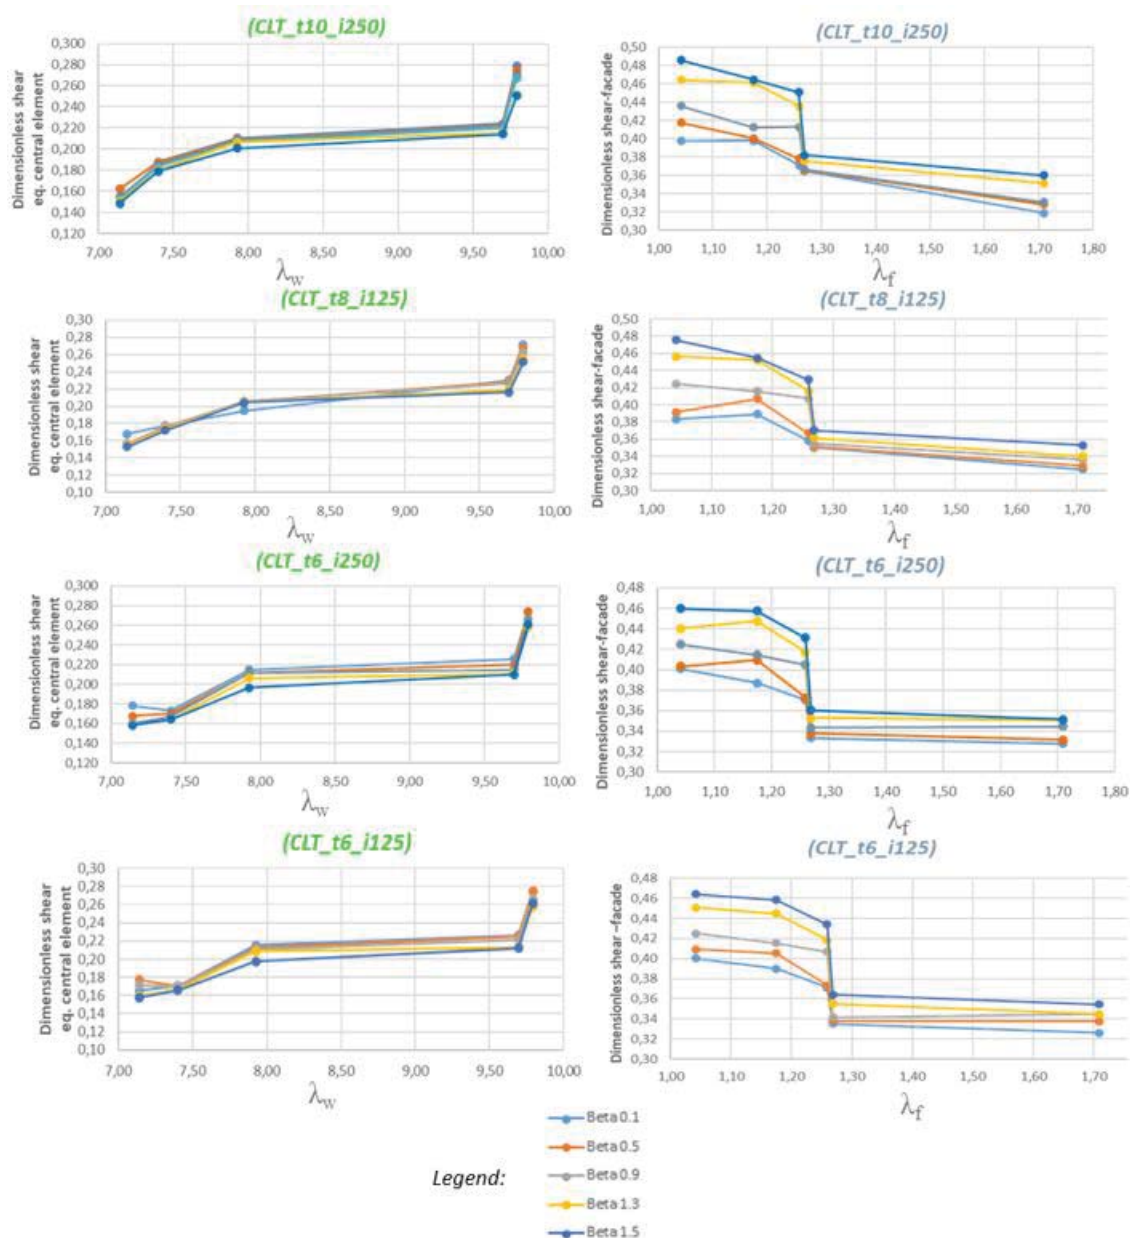

Figure 12: dimensionless base shear in comparison to the geometrical slenderness of the lateral walls ( $\lambda_w$ ) and the geometrical slenderness of the façade ( $\lambda_f$ ).

The results show that a slightly increases of the drift and the base shear acting on the central equivalent element occurs in correspondence to high value of lateral walls slenderness. On the contrary, the dimensionless base shear decreases when the façade slenderness increases.

Considering the trend of the drift and shear of the central equivalent element in relation to the lateral walls slenderness, abrupt variations are obtained when  $9.5 \leq \lambda_w \leq 10$ . It is important to highlight that two churches (Santa Maria del Carmelo and Santa Maria del Parco) characterized by a similar value of lateral walls slenderness were built with different materials and, consequently, different inertia forces are involved during the seismic action. Similar consideration can be made for San Pietro Felizzano and San Pietro Celestino church, analyzing the trend of the base shear related to façade slenderness  $\lambda_f$ . Furthermore, the shapes of the trends appear not be afflicted by the thickness of the panels or the number of the connections.

Figures 13 and 14 summarize the results obtained considering the shape factor ( $S_F$ ) parameter.

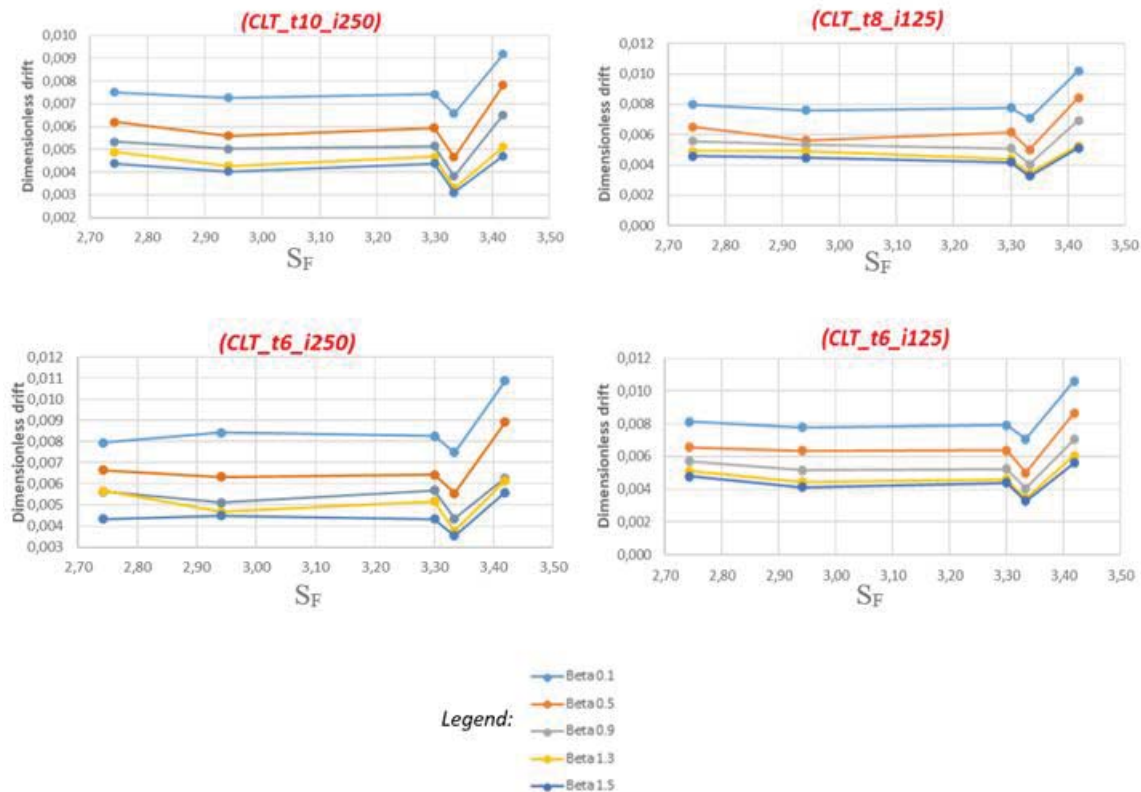

Figure 13: dimensionless drift in comparison to the shape factor  $S_F$ .

It is possible to notice that the dimensionless drift is generally constant with a slight increase for higher shape factor  $S_F$ . Considering the base shear acting on the central equivalent element, the trend obtained is opposite to that calculated for the façade.

Referring to the base shear of the façade, the most evident decrease occurred around  $S_F = 3,30$  for the churches Santa Maria del Parco and San Lorenzo. This fact is due to the very different geometrical characteristics that characterize the two churches (spans, total length and width). Also in this case, the shapes of the trends appear not be afflicted by the thickness of the panels or the number of the connections

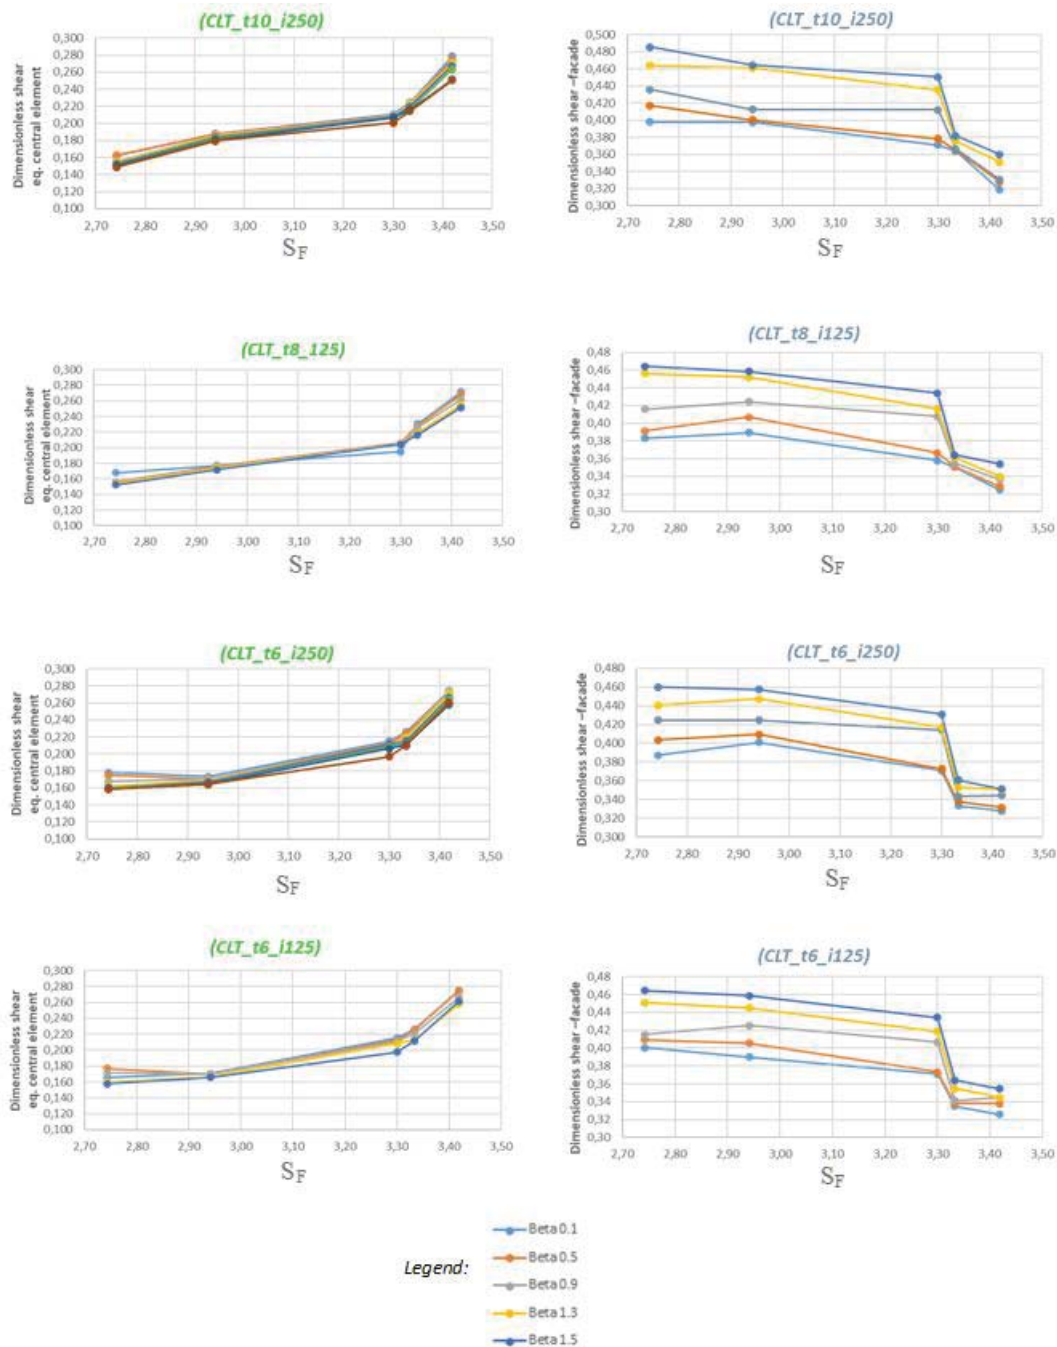

Figure 14: dimensionless base shear (central element and façade) in comparison to the shape factor ( $S_F$ ).

## 6 CONCLUSIONS

In this paper, the influence of the geometrical characteristics on the nave transverse response under seismic action of five historical churches, strengthen by different configurations of CLT panels roof structure, is studied through the execution of a series of non-linear dynamic analyses. The effects of the dissipative roof-diaphragm obtained by the CLT panels and connections are appreciable, especially in terms of dimensionless top displacement (drift) and dimensionless shear evaluated either at the base of the façade and the central part of the perimeter walls.

From the obtained results, the following main observations can be drawn.

- The CLT panels roof-structure in seismic restoration of historical churches can be considered as a valid solution either for the structural benefits in the nave transverse response and the satisfaction of the conservative restoration criteria.
- The equivalent finite element model with calibrated concentrated non-linear material properties (for the masonry and the roof-diaphragm) allows to evaluate the global response of historical churches with low calculation effort.
- The damped rocking mechanism pursued by the dissipative roof-structure is mainly ruled by the variations of the hysteretic variable  $\beta$  that gives a measure of the energy dissipation; the calibration of  $\beta$  is preferable in the range  $0 \div 1.5$  in order to limit the drift under the design drift value guaranteeing the self re-centering rocking behavior and limiting acceptable actions in the head and perimeter walls with respect to the masonry properties.
- The trends of the drift are in according to the shear: when the drift increases the façade base shear increases (while the shear at the base of the central part of the perimeter walls decreases).
- The drift and base shear variations depend more on the thickness of the CLT panels with respect to the connectors numerosity.
- The geometrical slenderness of the perimeter walls ( $\lambda_w$ ) influences the nave transverse response especially beyond  $\lambda_w > 9.5$  even if the seismic behavior cannot uniquely determine only by the geometrical slenderness because it is also influenced by the masonry properties (weight density and elastic modulus) and other geometrical features.
- The drift and the base shears are slightly afflicted by the shape factor.

## Abstract

*The seismic response of seven existing reinforced concrete chimneys equipped with optimized Tuned Mass Dampers (TMDs) are investigated under five acceleration time histories recorded during different important European seismic events. For each chimney, the features of the TMDs are detected by nonlinear dynamic analyses, starting from the investigation about the optimum mass ratio (between the optimum mass of the TMD and the mass of the chimney without the TMD involved in the most representative vibrational modes). By the application of sinusoidal forces, the contribute of the TMDs are evaluated by the estimation of the equivalent damping ratio.*

**Keywords:** Tuned Mass Damper, RC chimney, Seismic Response, Non-linear analysis.

## 1 INTRODUCTION

All over the world many industrial plants are characterized by the presence of chimneys. Starting from the '50 of the 20th century, in the new manufacturing and chemical plants reinforced concrete (RC) chimneys were built instead of the masonry traditional ones, due to plants requirements derived from the industrial developments and environmental reasons. From the middle of the 20th century, thanks to the new concrete techniques in use, it was possible to satisfy the new industrial processes requirements by reducing the environmental impacts with a significant height increasing (up to about 400 m), thus defining a wide range of possible heights from 100 m to 400 m. It is remarkable many RC chimneys were designed without specific earthquake-resistant provisions, considering only the wind as horizontal force [1] even if in some European countries, e.g. in Italy, many chimneys were built in areas only nowadays considered as seismic regions [2]. It represents an evident structural negligence for the seismic performance of many existing RC chimneys in terms of resistance and ductility and for economic aspects. Under seismic loads, the chimneys are characterized by an inelastic response, different from the elastic behavior. The domain of higher modes vibration and large natural period vibration consistently drives to a complex global dynamic response during earthquake events, reporting extremely increase of structural stress states, possible brittle collapse [3–10].

A recent study [11] has pointed out 6 major chimney failures causes, from 739 study cases, statistically summarized. The damage of these RC chimneys was mainly caused by seismic and wind action, temperature stress and construction defect [9].

Several researches have made relevant considerations in the earthquake engineering field [12,13] which revealed a sort of crack pattern of these slender constructions. In particular, they identified a failure-prone region at  $1/3$  to  $2/3$  also  $0.8$  of the height of a standard designed chimney, which concentrates inelastic deformations. It may occur when remarkable inertial force takes place in hazard earthquake, observing fractures in the horizontal, vertical, and inclined directions depicted after the strong motion. A predominance of cracks with 20–30 mm widths according to [11] was noticeable in many seismic events. It was observed the specific wind design cannot allow an adequate seismic response [12] in particular in terms of concrete stiffness with respect the concrete strength [14]. The increase of the height over 130 m exposes chimneys to large displacements wreaking cracks which demand extensive rehabilitation. Moreover, the radius-thickness ratio feature has also relevant influence in the dynamic response that decreases the displacement with the growth of the radius-thickness. It can be observed in chimney tapered from bottom to top lesser displacement values than chimneys which are tapered from the bottom then becomes uniform at one-third height. Shell stress as well decreases with the increase of radius thickness ratio in a fully tapered chimney in respect of partially tapered chimney. Chimneys with heights ranging from 325 m to 350 m are vulnerable against seismic forces especially in case of elliptical cross-section. However circular chimneys have higher displacement than the elliptical section ones with higher accelerations under the seismic events. For improving the seismic response an adequate representation of the chimneys and the earthquakes is mandatory as it is explained in [9,10]. In these studies, the efficiency of passive tuned mass dampers is also proposed as a valid cost-benefits solution [15]. In several cases, the use of a single TMD represents a valid solution in terms of structural and economic convenience. The contribute of the single TMD can be described by shifting period coupled to the damping increase characterized the new system represented by the chimney with the TMD are easily detected.

## 2 STRUCTURE OF THE PAPER

In Section 3, starting from the features of the chimneys (3.1) and the ones of the seismic actions (3.2), for each chimney the parameters of the Tuned Mass Dampers (TMDs) are detected (3.3). In the Section 4 the contribute of the TMDs in terms of equivalent damping is evaluated whereas the energetic contributions are shown in Section 5 (where a comparison between the cases chimneys without TMDs and chimneys with TMDs is shown as well). Finally, Section 6 contains the remarks about the results characterized Section 4 and Section 5,

## 3 IDENTIFICATION OF THE TUNED MASS DAMPERS FEATURES

### 3.1 Chimneys

The seven RC chimneys here investigated were built from the '60 to the first half of the '80 years. They are classified considering four main geometrical features: the height (H), the geometrical slenderness  $\lambda = H/D_{\text{base}}$ , the taper ratio  $t_d = D_{\text{top}}/D_{\text{base}}$  and the mass distributed along the height ( $q_h$ ), depending on the chimney materials and the structural configuration and where  $D_{\text{top}}$  represents the external diameter at the top of the structure while  $D_{\text{base}}$  indicates the external diameter at the base of the structure. In Table 1 the main information about the chimneys are shown.

Chimney	$D_{\text{base}}$ [m]	$D_{\text{top}}$ [m]	H [m]	$t_d$	$\lambda$	$t_h$ [cm]	$q_h$ [kN/m]
CH_1	4.8	2.5	60	0.52	12.50	30	76.50
CH_2	16.1	13.6	100	0.85	6.21	40-30	100.00
CH_3	10.3	6.6	115	0.64	11.17	45-20	71.00
CH_4	15.0	14.8	120	0.99	8.00	35-26.5	29.00
CH_5	15.7	9.4	183	0.60	11.66	60-30	56.00
CH_6	16.0	8.5	220	0.53	13.75	76-20	76.50
CH_7	26.0	16.8	245	0.65	9.42	70-35	80.00

Table 1. Main characteristics of the seven chimneys. Note:  $D_{\text{base}}$ =diameter at the base;  $D_{\text{top}}$ =diameter at the top; H=height;  $t_d$ =taper ratio;  $\lambda$ =slenderness;  $t_h$ =thickness of the circular hollow section;  $q_k$ =distributed mass along the height.

The finite element model (FEM) of each chimney is implemented by MIDAS Gen software [16]. Each FEM has beam elements with a perfect restrain at the base. The self-weight and the dead loads are converted to mass in order to carry out the eigenvalue analyses for evaluating the periods, the related modal participation mass and the deformed shapes. The nonlinear material property of the concrete is attributed by Kent-Park property [17] and the ones attributed to the steel rebars is described in [18]. Eigenvalue results are shown in Table 2.

Chimney	$T_1$ [s]	$M_1$ [%]
CH_1	1.63	58.48
CH_2	0.90	66.51
CH_3	1.77	54.24
CH_4	1.33	63.82
CH_5	2.55	53.87
CH_6	3.21	48.02
CH_7	3.79	45.23

Table 2. Eigenvalue analysis results. Note:  $T_1$  is the first fundamental period and  $M_1$  is the related involved mass

### 3.2 Seismic actions

The seismic actions are represented by five acceleration times histories recorded during different European seismic events (Greece, Amatrice, L'Aquila, Friuli and Montenegro), included in the European Strong-Motion Database. The features of the seismic inputs are shown in Table 3. The seismic inputs have been selected in order to obtain Magnitude between 6 and 6.9 and a PGA value between 0.35 g and 0.53 g: however, they are characterized by different integral parameters values, gaining a large variability of the ground motion characteristics , [19,20].

Event	Event id	Stat.	Year	PGA	PGV	PGD	M <sub>w</sub>	Arias Int.
[-]	[-]	[-]	[-]	[g]	[cm/s]	[cm]	[-]	[cm/s]
Friuli (Acc1)	IT-1976-0030	FRC	1976	0.35	23.7	5.3	6	84.5
Montenegro (Acc2)	ME-1979-0003	PETO	1979	0.45	38.5	6.9	6.9	455.7
Amatrice (Acc3)	EMSC-20161030_0000029	AMT	2016	0.53	37.9	7.5	6.5	156.4
Greece (Acc4)	GR-1995-0047	AIGA	1995	0.52	51.3	8.3	6.5	117.1
L'Aquila (Acc5)	IT-2009-0009	AQG	2009	0.49	35.8	6.0	6.1	132.4

Table 3. Characteristics of the seismic inputs.

### 3.3 Tuned mass dampers parameters

Once the vibration mode shapes and the main frequencies of the structures are known, the features of the TMDs can be evaluated according to [21,22] and the seismic response can be analyzed by introducing the TMDs in the FEMs of each chimney (system 2). The TMD is implemented through a nodal mass connected to the chimney with a spring and linear dashpot characterized by horizontal stiffness ( $k_{TMD}$ ) and damping coefficient ( $C_{TMD}$ ). The boundary conditions of the node representing the TMD are set to allow only the horizontal displacements of the mass. The horizontal stiffness ( $k_{TMD}$ ) and the related damping coefficient ( $C_{TMD}$ ) are evaluated considering the following relations [23]:

$$k_{TMD} = m \cdot \alpha_{opt}^2 \cdot \omega_s^2 \quad (1)$$

$$C_{TMD} = 2 \cdot \xi_{opt} \cdot \sqrt{(k_{TMD} \cdot m_d)} \quad (2)$$

From [24] the values of  $k_{TMD}$  and  $C_{TMD}$  are obtained starting from the definition of the ratio ( $\mu$ ) given by the ratio of the mass of TMD ( $m_d$ ) and the mass of the chimney ( $m$ ) involved in the main vibrational mode (already explained in Phase A) and  $\omega_s$  defined as the pulsation depending by the main frequency ( $f_1$  corresponding to the frequency value of the first and second mode shapes of the chimney without TMD) by the equation (3):

$$\omega_s = 2\pi \cdot f_1 \quad (3)$$

The TMD mass ratio is given by the Eq.4 to obtain concerning the fundamental mode ( $\mu_1$ ) is given by:

$$\mu_1 = \frac{m_d}{\alpha_1 \cdot m} \quad (4)$$

where  $\alpha_1$  is the participant mass ratio of the fundamental mode of the structure without the TMD. The general mass ratio  $\mu$  is expressed as:

$$\mu = \frac{m_d}{m} = \frac{\mu_1 \cdot \alpha_1 \cdot m}{m} = \mu_1 \cdot \alpha_1 \quad (5)$$

In order to define  $k_{TMD}$  and  $C_{TMD}$ , the optimal coefficient for the frequencies ( $\alpha_{opt}$ ) and the optimal equivalent viscous damping ratio ( $\xi_{opt}$ ) are evaluated as it comes out from the following expressions, where  $\xi$  is the equivalent damping ratio for the structure:

$$\alpha_{opt} = \left( \frac{\sqrt{1 - 0.5\mu}}{1 + \mu} + \sqrt{1 - 2\xi^2} - 1 \right) - (2.375 - 1.034\sqrt{\mu} - 0.426\mu) \cdot \xi \cdot \mu - (3.730 - 16.903 + 20.496\mu) \cdot \xi^2 \cdot \sqrt{\mu} \quad (6)$$

$$\xi_{opt} = \sqrt{\left( \frac{\sqrt{3\mu}}{8(1 + \mu)(1 - 0.5\mu)} \right) + (0.151\xi - 0.175\xi^2) + (0.163\xi + 4.98\xi^2) \cdot \mu} \quad (7)$$

Basing on the previous relations the values of mass the TMD can be taken in the range 1%÷5% of the mass of the chimney excited in correspondence of the main frequency (related to the first and second mode shapes). Testing different values of the TMD's mass, the related values of  $k_{TMD}$  and  $C_{TMD}$  (see relation (1) and (2)) can be detected and the different seismic response of “chimney with TMD” (system 2) can be evaluated in the FEMs where displacement, shear and moment variations are graphically shown in Figure 1. Once the average trends are detected for each chimney, the mass ratios optimizing the sizes of the TMDs are evaluated. The optimized size must minimize the mass of the damper but it must allow to reduce as far as possible the displacements, the base shear and base bending moment [4,25]. Therefore, for each chimney when the optimum mass ratio ( $\mu_{OPT}$ ) is chosen, the features of each TMD are evaluated as well in terms of horizontal stiffness ( $k_{TMD}$ ) damping coefficient ( $C_{TMD}$ ) and pulsation ( $\omega_s$ ) by the previous equations (1÷3), see Table 4.

#### 4 EQUIVALENT DAMPING EVALUATION

The contribution of the mass dampers of each chimney in terms of equivalent damping ( $\xi_e$ ) is here estimated starting from the dynamic amplification factor (H) given by the ratio between  $X_s$  and  $X_d$ , where  $X_s$  is the top displacement under seismic action and  $X_d$  is the dynamic top displacement under forces with frequencies included in the range  $(0.8 \div 1.2) \cdot f_l$  where  $f_l$  corresponds to the frequency to smooth (this value is obviously different for each chimney). The ratio between the frequencies of the forces and the frequency to smooth is called  $\rho$  (the variation of H by  $\rho$  is shown in Figure 2). The equivalent damping ( $\xi_e$ ) due to the TMDs can be detected as well from H because  $\xi_e$  is given by the relation (7) and it can be plotted once again in relation to  $\rho$ . The final value of the equivalent damping corresponds to the average one of the two lower peaks of the diagrams  $\xi_e$ - $\rho$  (Figure 3):

$$\xi_e = \frac{H}{2} \quad (7)$$

It is worth nothing the influence of the main frequency of the chimney in the TMD's contribution in terms of equivalent damping given to the main structure. The results plotted in the Figure 2 and Figure 3, respectively in terms of dynamic amplification factor (H) and equivalent damping ( $\xi_e$ ), are useful in order to appreciate the smooth effects given by the TMDs for each chimney under the five seismic events. The equivalent damping values are summarized in Table 5; the variation of the equivalent damping in relation to the frequencies of the chimneys is shown in Figure 4.

## 5 ENERGETIC CONTRIBUTION OF THE TUNED MASS DAMPERS

In the present phase the dynamic behavior of the five case studies (chimneys with TMDs) is deepened in terms of energy damping starting from the assumption that for the generic chimney the input energy ( $E_i$ ) due to the seismic action is the work done by the ground motion on the construction. Considering the time dependent conservation of the energy, ( $E_i$ ) is given by the summation of the kinetic energy ( $E_k$ ), the elastic strain energy ( $E_s$ ), the energy dissipated by the structure throughout the inelastic features ( $E_h$ ) and the damped dissipative energy of the building and the mass damper if present ( $E_d$ ). Formulations about the energies are present in [26,27]. The aim of this phase is the evaluation of the damping energy during each seismic event for the seven chimneys either in the case chimneys without TMD and chimneys with TMDs. In Figure 5, for each chimney, the damping energy ( $E_d$ ) is plotted for the five accelerograms. The output of the energetic analyses represents the variation of the damping energy during the seismic events therefore the results of this kind of analysis is plotted by time histories in both cases (chimneys without and with TMDs). Each time history represents the percentage of the damping energy with respect to the input energy.

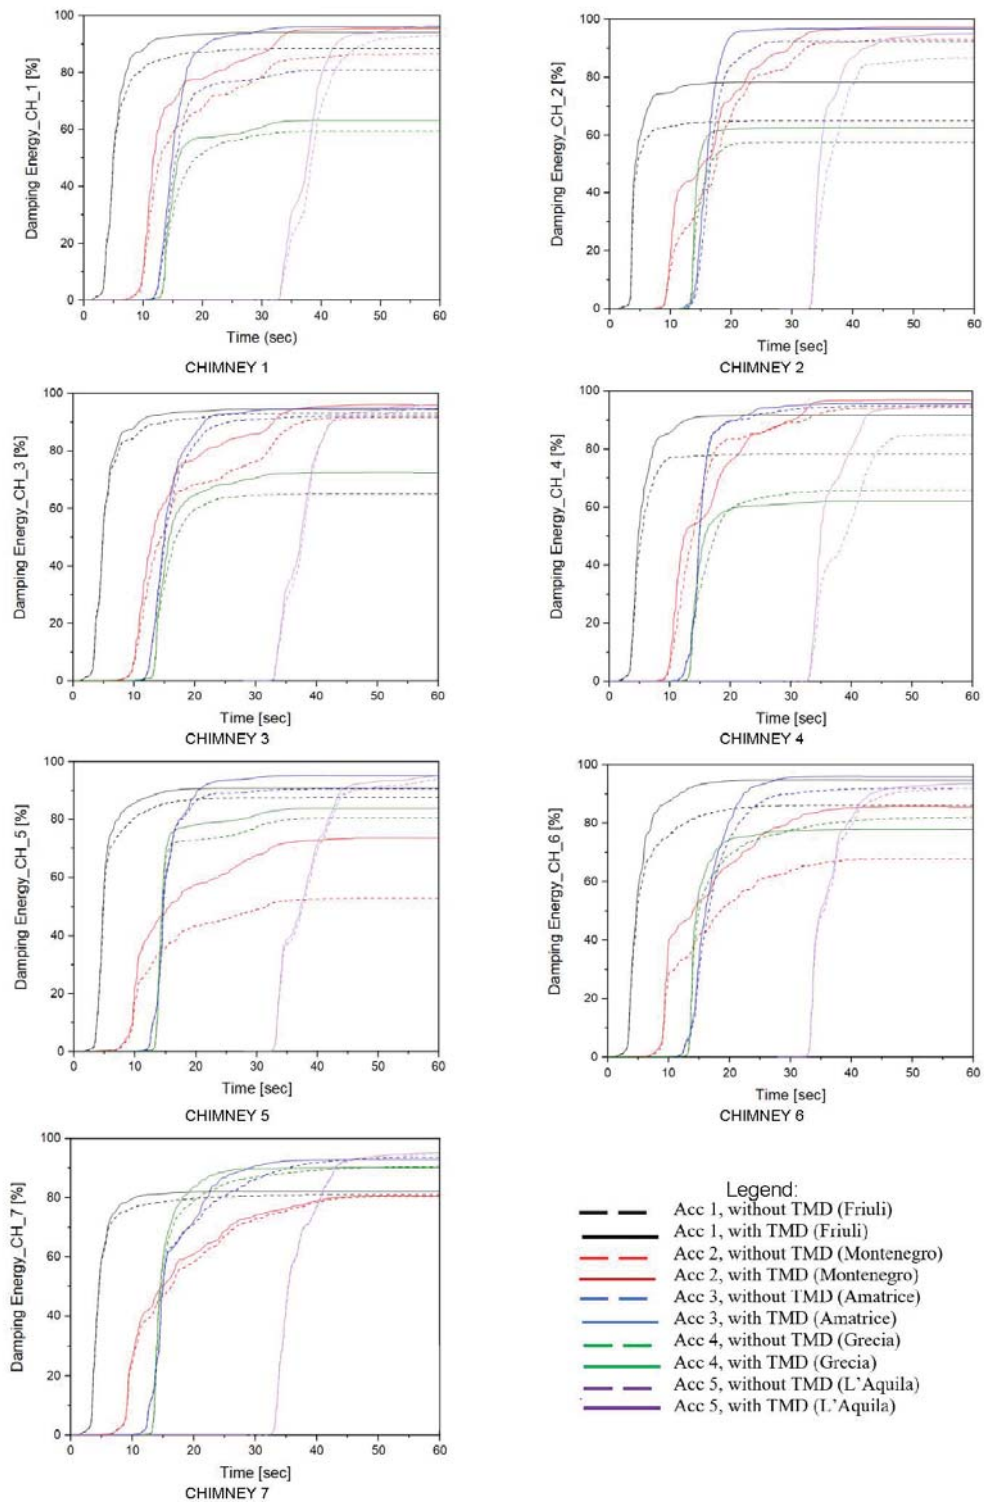

Figure 5. Evaluation of the percentage of the damping energy ( $E_d$ ) with respect the input energy ( $E_i$ )

## 6 REMARKS

- The use of the Tuned Mass Dampers for existent Reinforced Concrete chimneys represents a valid solution for improving the seismic response of this kind of construction especially if originally built in areas only nowadays classified as seismic areas;
- The size of the TMD is influenced by the geometrical features of the chimneys: in fact, chimneys with high slenderness values need TMD with optimum mass ratio  $\mu_{opt}$  higher than the ones with low slenderness. For slenderness value around  $\lambda = 10$  the optimum mass ratio  $\mu_{opt}$  is around 3% but for higher slenderness values, as it is for CH\_6 with  $\lambda_{CH\_6} = 13.75$ , higher mass ratio  $\mu_{opt-CH\_6} = 5\%$  is adopted; vice versa CH\_2 with slenderness  $\lambda_{CH\_2} = 6.21$  needs lower mass ratio  $\mu_{opt-CH\_2} = 1.5\%$ ; similar consideration may not be valid about the effect of the taper ratio  $td$  on the size of the TMD because chimneys with different  $td$ , as CH\_1 with  $td = 0.52$  and CH\_4 with  $td = 0.99$ , are characterized by mass ratio values very close themselves (e.g.  $\mu_{opt-CH\_1} = 4\%$  and  $\mu_{opt-CH\_4} = 3\%$ );
- In the seismic events here adopted, the most important variations with the TMDs occur in terms of top displacement for each chimney; although, the base shear variation is not appreciable for each chimney especially in comparison to the displacements and moment variations;
- the equivalent damping does not appear dependent by the individual features of the chimneys (even if for high value of the geometrical slenderness - as it is for chimneys 1, 5 and 6 respectively with  $\lambda_{CH\_1} = 12.5$ ,  $\lambda_{CH\_5} = 11.66$  and  $\lambda_{CH\_6} = 13.75$  - the equivalent damping values are very similar themselves); it is worth nothing the equivalent damping due to the TMD depends on the characteristics of the seismic event combined to the natural frequency of each single chimney, thus the seismic response is a correlation between the chimney's features (as the height, taper ratio, slenderness and dead loads) and the ones of each seismic event shaking the construction. A relation between the equivalent damping and the main periods of the chimneys ( $T$ ) is expressed in the relation shown in Figure 4 where the equivalent damping  $\xi_e$  here estimated exhibits exponential variation growing for the lower values of  $T$ ; vice versa, the intensity of the strong motion becomes irrelevant when the main period increases.

$$\xi_e = 0.3178 \cdot e^{-\frac{T}{0.33683}} + 0.01809 + 0.0039T \quad (8)$$

- under the five earthquakes the damping energy for the seven chimneys increases thanks to the TMDs; the contribution of TMDs is much evident in the asymptotic branch of the curves, especially under accelerograms 1 and 2 (drawn by black and red lines. In the case chimneys with TMDs, the damping energy increases. Generally, the dissipation of the input energy due to the seismic event occurs for damping contribute whereas the one due to the strain energy is practically zero. At the same time the TMD slightly reduces the contribute of kinetic energy in the dissipation of the input energy.

### Abstract

*In this research, the dynamic characteristics and effects of shear walls in lateral stiffness of long-span Hanok have been studied by shaking table test. The 1/20 scale experimental model for the long-span test-bed Hanok has been built for shaking table test. The shaking table test was done on two cases, that is, full or no shear wall. The shaking table test was done on a 1/20 scale experimental model for the previous two cases. The experiment was done sequentially, first for full shear wall model, and then no shear wall model. The shaking table was actuated sequentially by four types of input gain, that is, from random gain 1 to random gain 4 with increasing scenario. The maximum displacement of experimental model on its roof top was measured for both full and no shear wall cases for four random gains. Full shear wall case showed much less displacement for all random gains compared to the no shear wall case. The average displacement reduction ratio for four random gains is 64.4%, which shows the significant effect of shear wall in lateral load resisting capability. The natural vibration frequency of full shear wall is 11.28Hz compared to the no shear wall of 5.5Hz, which shows stiffness is about 4 times.*

## 1 INTRODUCTION

The Korean traditional timber structure, especially used as residential is called Hanok. Hanok has history of more than two thousand years. The structure of Hanok as shown in Fig. 1(a) is characterized as a post and beam structure. The vertical load is supported mainly by post and beam as shown in Fig. 1(b), and the lateral load is supported mainly by walls incorporated with peripheral timber frame. In a very rare case, truss is used as lateral load resisting system as shown in Fig. 1(c).

(a) Korean Traditional Timber Structure

(b) Load paths of through post and beam in Hanok

(c) Trussed wall used as a lateral load resisting system in Hanok

Figure 1: Korean traditional timber structure and its load paths

The main characteristic of Hanok is in its joints. The joint of Hanok is mostly mortise and tenon joint of only wood as shown in Fig. 2. It rarely uses steel connector or steel nails. The

heavy roof weight of Hanok helps the joint have somewhat rotational rigidity against lateral load. Generally, the span of traditional Hanok between columns is about 2.4~4.8 meters. This short span does not matter as a residential use. Nowadays, long span, which is about 10~20 meters, is required to accommodate various modern life style of people and to enlarge the use of Hanok as a public usage. As the span is longer various problems should be solved in structural point of view.

Figure 2: Traditional mortise and tenon joint of Hanok

As the span of Hanok becomes longer, new load carrying paths and new joint types should be carefully planned and designed to support increased load and unfamiliar large inner space. Timber structure in East Asia and the West has much in common in their skeleton and construction method. So, various researches on the timber structures have been carried out extensively around the world. Seo et al. [1] studied the structural characteristics of wooden frames with tenon joints under lateral static and cyclic load, Han et al. [2] studied mechanical performance of tenon joints to enhance traditional wooden house, Kang et al. [3] studied the static performance of mortise and tenon joint in Chinese traditional timber structure, Lee et al. [4], [5] studied both the longitudinal and transversal load carrying capacity of Korean traditional timber structure, and Kim et al. [6] evaluated rotational stiffness of steel joints used in a new-styled Hanok by static experiment on a 1/4 scale model.

Fang et al. [7] performed dynamic test on traditional Chinese timber structure and verified its structural characteristics, Hwang et al. [8] performed shaking table test on Korean traditional timber structure and showed the variation of natural frequency according to vibration amplitude, and Lee et al. [9] compared dynamic characteristics of both traditional and new-styled Hanok according to excitation amplitude. Ozsev et al. [10] conducted small scale hands-on experiments on a model wooden frame structure under dynamic effects.

As a design aid to the Korean traditional timber structures, section tables and structural design software for the design of main structural members of Hanok has been developed [11],[12],[13],[14] and these design tools were used in making Korean design standard on Hanok. Recently, evaluation tool on the torsional irregularity of Hanok has been developed to aid seismic design of Hanok [15].

In this study, the dynamic characteristics of long-span Hanok and the effects of shear walls in lateral stiffness have been studied by shaking table test and the results are analyzed.

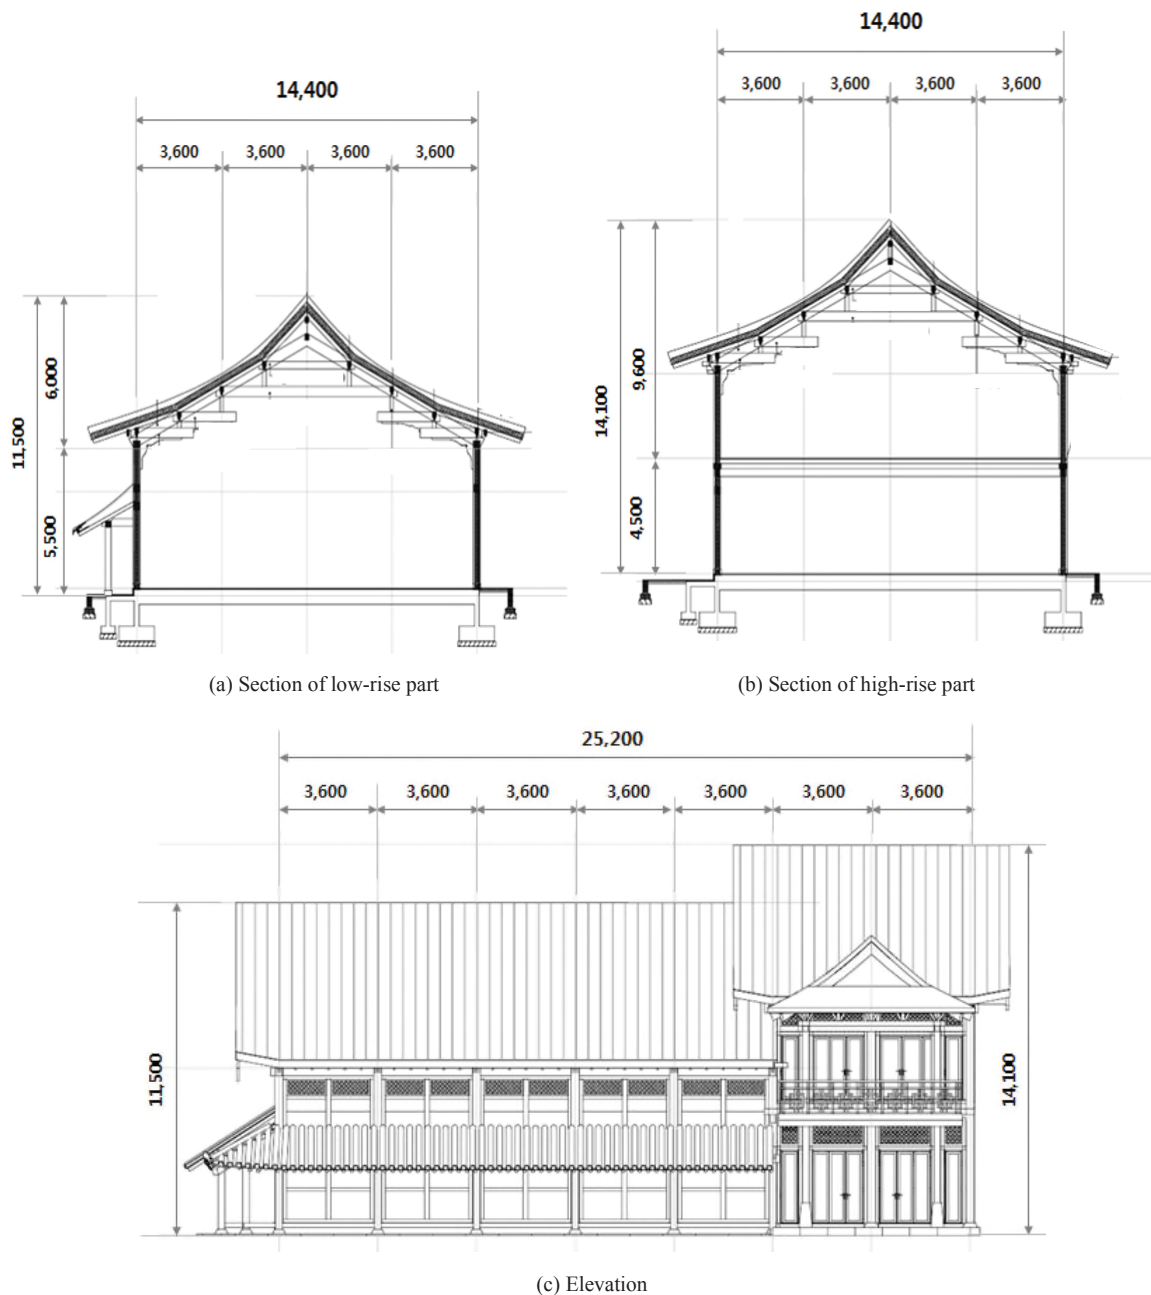

## 2 EXPERIMENTAL MODEL FOR SHAKING TABLE TEST

The long-span test-bed Hanok with its transversal span of 14.4meter and longitudinal span of 25.2meter has been designed as shown in Fig. 3. This long-span test-bed Hanok is scheduled to be built in Yongin, Korea, 2021. The 1/20 scale experimental model for this long-span test-bed Hanok has been built for shaking table test as shown in Fig. 4(a). The vertical load

was imposed on the roof and floor of the experimental model with steel plate as shown in Fig. 4(b). The total weight is 87.24kg.

The shaking table test was done on two cases, that is, Case A and Case B as shown in Table 1. Case A has full shear wall, that is, no opening, whereas, Case B has no shear wall, that is, full opening. Fig. 5(a) shows the location of shear wall in plan, and Fig. 5(b) and Fig. 5(c) show the front and rear view of test model of Case A.

The motor of shaking table is operated by real-time displacement control method using Labview program of NI corporation. The velocity, corresponding to input acceleration was numerically integrated and this was used as the input signal of motor. Four accelerometers were used to measure both X and Y directional movement. The sampling rate for data is 3200Hz. The relative displacement of the model compared to the base was measured by laser displacement equipment by measuring both the roof and base displacement of the model.

Figure 3: Section, elevation and roof plan of actual building

Model Case	Shear walls	Opening ratio
Case A	Full shear walls (No opening)	0%
Case B	No shear walls (Full opening)	100%

(b) Imposition of vertical load by steel plate

Figure 4: . 1/20 scale experimental model and imposition of vertical load

### 3 SHAKING TABLE TEST ON EXPERIMENTAL MODEL

The shaking table is one-directional as shown in Fig. 6. The experiment was done sequentially. First, shaking table experiment was done for Case A with full shear wall as shown in Fig. 7(a), and then shear wall was removed and the same shaking table experiment was done, which is for Case B as shown in Fig. 7(b). There are four types of input gain to the shaking

table as shown in Fig. 8, that is, from random gain 1 to random gain 4 with sequentially increasing scenario.

(b) Case B : no shear wall with full opening

Figure 7: Two experimental models, Case A and Case B

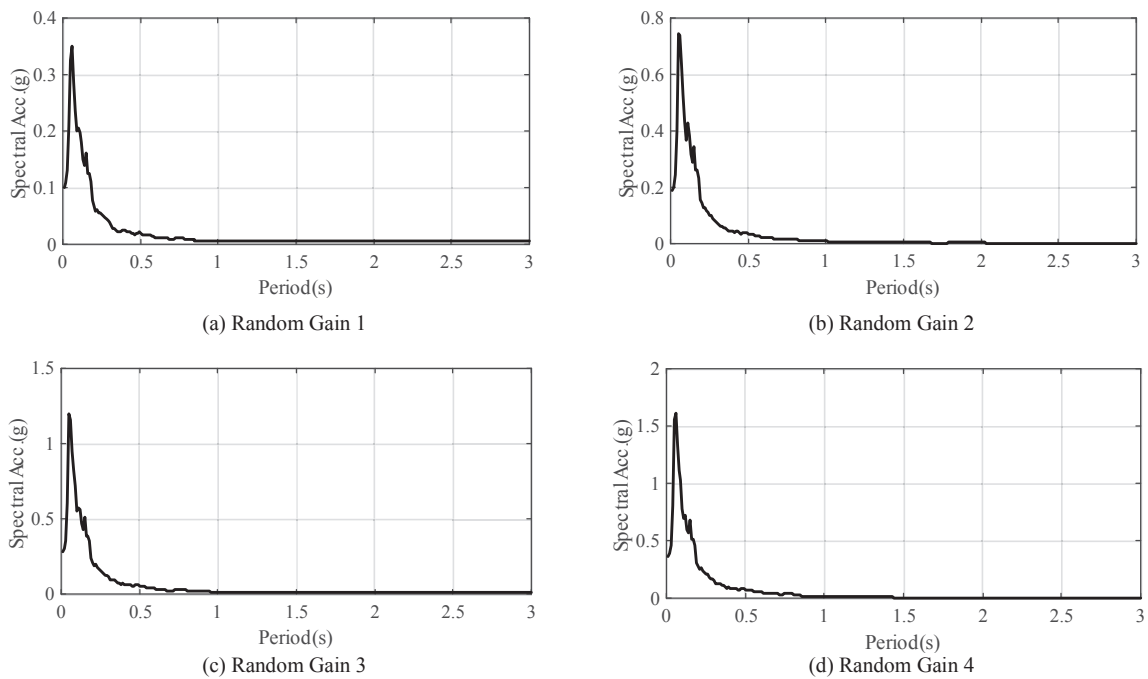

Figure 8: Response spectrum of four types of random gain

#### 4 RESULTS OF SHAKING TABLE TEST

The maximum displacement of experimental model on its roof top was measured for Case A and Case B for each random gain. The results are shown in Table 2. Compared to Case B, which has no shear wall, Case A showed much less displacement for all random gains. The

average displacement reduction ratio for four random gains is 64.4%. Here we can deduce that, the shear wall shows significant effect in lateral load resisting capability.

The natural vibration frequency of Case A is 11.28Hz compared to the Case B of 5.5Hz. As the vibration frequency is about two times larger, we can deduce that the stiffness is about 4 times larger. Here we only compared the maximum displacement and natural vibration frequency only for preliminary test. The other dynamic characteristics including torsional effect are scheduled to be studied in the coming paper.

Input load	Maximum displacement (mm)		Displacement reduction ratio (%)
	Case A (No opening)	Case B (Full opening)	
Ran. Gain 1	0.44	1.43	69.2
Ran. Gain 2	0.80	2.61	69.3
Ran. Gain 3	1.25	3.22	61.2
Ran. Gain 4	1.56	3.71	58.0

Table 2: Displacement Reduction Ratio According to Shear Wall

## 5 CONCLUSIONS

In this research, the dynamic characteristics of long-span Hanok and the effects of shear walls in lateral stiffness have been studied by shaking table test and the results are analyzed. The 1/20 scale experimental model for the long-span test-bed Hanok has been built for shaking table test. The shaking table test was done on two cases, that is, full or no shear wall. The shaking table test was done on a 1/20 scale experimental model for the previous two cases.

The experiment was done sequentially, first for full shear wall model, and then no shear wall model. The shaking table was actuated sequentially by four types of input gain, that is, from random gain 1 to random gain 4 with increasing scenario. The maximum displacement of experimental model on its roof top was measured for both full and no shear wall cases for four random gains. Full shear wall case showed much less displacement for all random gains compared to the no shear wall case.

The average displacement reduction ratio for four random gains is 64.4%, which shows the significant effect of shear wall in lateral load resisting capability. The natural vibration frequency of full shear wall is 11.28Hz compared to 5.5Hz for no shear wall, which shows stiffness is about 4 times larger in the former. In the coming paper, we are going to study the natural vibration period and other dynamic characteristics of long-span Hanok.

## 6 ACKNOWLEDGEMENTS

This work was supported by a grant (21AUDP-B128638-05) from Urban and Architecture Research Program funded by Ministry of Land, Infrastructure and Transport Affairs of Korean Government.

### Abstract

*Residing in a country like Greece, where the earthquake is a common phenomenon in most of its areas, the need for constructing earthquake resistant buildings that will provide security and functionality to their residents is imperative. For this reason, the present study estimates the cost of constructing the same five-storey building in three different seismic hazard zones. Initially, this building is studied, in accordance with the provisions of Eurocode 8, for seismic zones I, II and III. The dimensioning and calculation of the weight of the required steel and the volume of the required concrete is carried out. The results from the three seismic zones are presented in detail, both for each structural element of the construction separately and for the whole construction, and a comparison is made between them.*

**Keywords:** Seismic hazard zones, Multi-storey building, Construction's cost, Reinforcement

---

## 1 INTRODUCTION

In modern times, various materials are used for the construction of high-rise buildings. The choice of these materials can be made depending on the use of the building, the area in which it is located, the architectural and static study, the cost of construction [1]–[5]. However, in Greece, for the majority of buildings, reinforced concrete is used as a construction material. A reinforced concrete building is made of concrete and steels in the form of rebars or ties. These two materials are harmoniously combined in order, on the one hand, the concrete to receive the compressive forces and on the other hand, the steel to receive the tensile stresses [6], [7]. Greece is an intensely seismic country and as earthquake action is a dangerous and destructive natural phenomenon, the buildings, whether they are new constructions or older, must deal with it effectively. This effective response comes through the design and construction of anti-seismic buildings, but also the strengthening of existing ones [8]–[18].

Nowadays, more and more high-rise buildings are being constructed, with many floors, which are quite sensitive, not only to large earthquakes, but also to less intense ones, if they are not built properly. One of the main problems of these buildings is that, during the earthquake, probably some of their floors move in one direction, while at the same time the other floors move in the opposite direction [19], [20]. Therefore, the engineer should take very seriously the seismic zone in which each building is constructed. The seismic zone significantly affects the dimensioning of the structure, the cross sections of its structural elements and their reinforcement, thus affecting its cost. The engineer has the ability, if for some reason he deems it necessary, to dimension his building in a higher seismic zone than the one to which the building belongs. However, he should not forget that his choice will increase the final construction cost.

The present study presents the simulation and dimensioning, based on modern regulations, of three buildings which have the same standard floor plan, the number of floors (five floors), but are located in different seismic zones. The cost comparisons for the same building between the three different seismic zones leads to useful and interesting conclusions.

## 2 ANALYTICAL RESEARCH

### 2.1 Construction description

The floor plan of the building has dimensions 25 x 25 m, therefore the total area of the floor plan is equal to  $E = 625.00 \text{ m}^2$  (Figure 1). The height of the floors is  $h = 3.00 \text{ m}$ , except for the height of the first floor (ground floor) which is  $h = 4.50 \text{ m}$ . Therefore, the total height of the building is  $h_{\text{tot}} = 16.5 \text{ m}$ . Rigid supports are used and the effect of soil is neglected [21], [22].

The main element of the load-bearing structure can be characterized as the main core, which is located in the center of the building and includes the elevators and stairwells. Regarding the dimensions of the structural elements, there are some small differences from floor to floor. There are also some structural walls in the building. These are the structural walls  $T_3$  and  $T_{10}$  at the two sides of the building's plan. Finally, in terms of beams, they are divided into perimeter and internal. The dimensions of the perimetric beams and the beams of the core are 25 x 70 cm and the internal ones have dimensions 25 x 60 cm. The cross-sections of the structural elements are shown in Table 1.

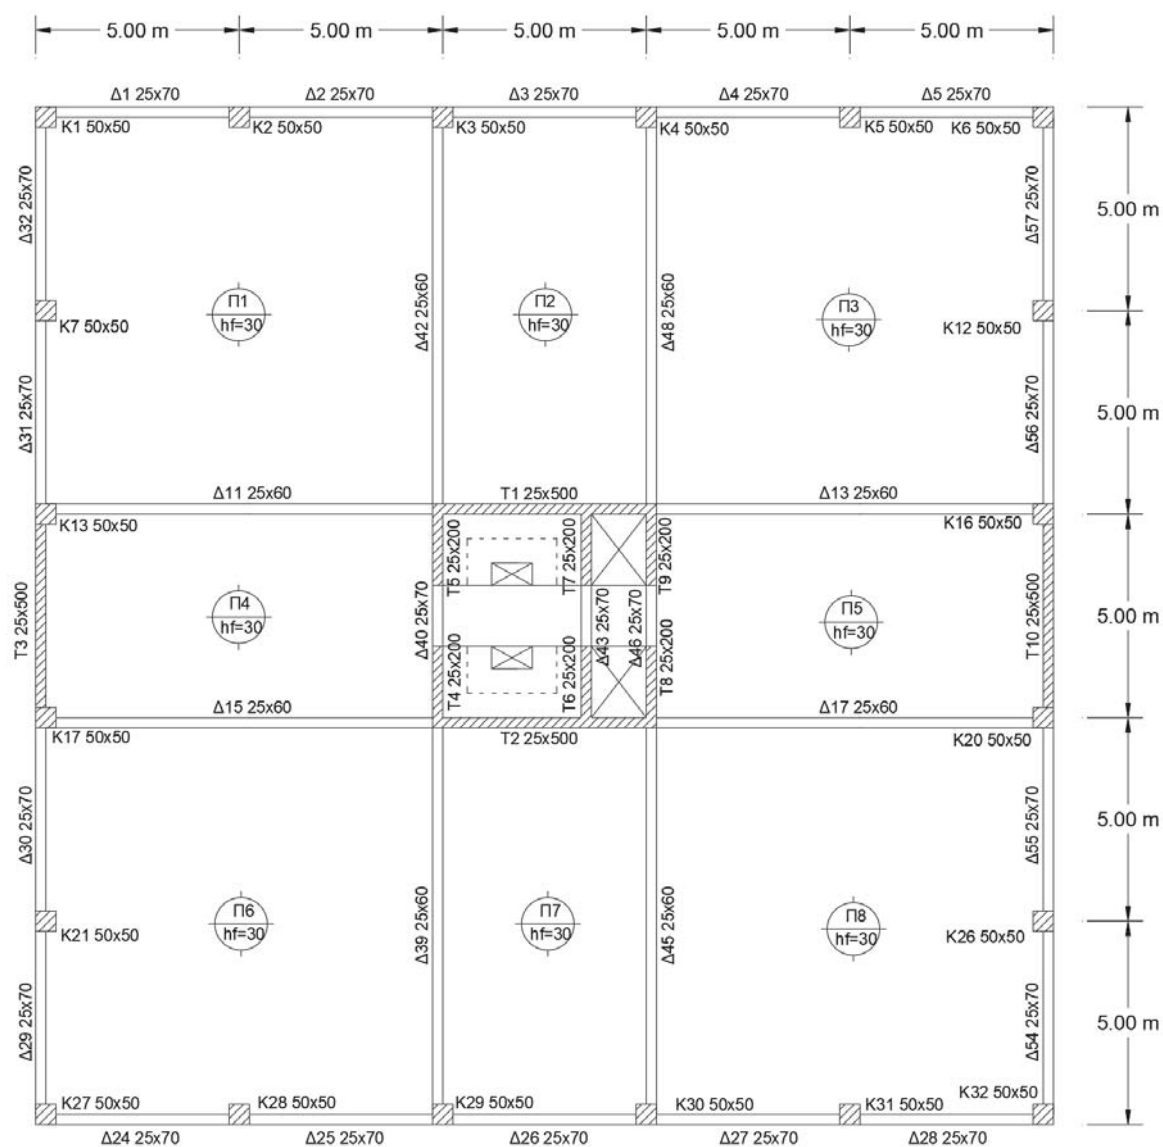

Figure 1: Typical floor plan.

Floor	Height (m)	Beam dimensions (cm)		Wall thickness (cm)	Column dimensions (cm)
		Perimetric	Internal		
1 <sup>st</sup> (Ground floor)	4.50	25x70	25x60	25	50x50
2	3.00	25x70	25x60	25	50x50
3	3.00	25x70	25x60	25	45x45
4	3.00	25x70	25x60	25	40x40
5	3.00	25x70	25x60	25	35x35

Table 1: Dimensions of the structural elements.

## 2.2 Materials

For all the load-bearing structural elements of the construction, concrete quality C30/37 and steel quality B500C were used for the reinforcement bars. According to Eurocode 2 [23], for concrete quality C30/37, the modulus of elasticity is given equal to  $E_{cm} = 32$  GPa. The Poisson ratio is considered equal to zero ( $\nu = 0$ ) for cracked. The steel quality B500C has a characteristic strength equal to  $f_{yk} = 500$  MPa.

## 2.3 Analysis method

The building was analyzed for the vertical loads applied under the combination of  $1.35G + 1.50Q$ , as well as for the seismic actions under the combination of  $G + \psi_2Q \pm E$ . The dynamic spectral method was used for the dynamic analysis of the building. The building was analyzed and examined in three different seismic hazard zones. In zone I with maximum seismic horizontal ground acceleration  $a_g = 0.16g$ , in zone II with  $a_g = 0.24g$  and in zone III with  $a_g = 0.36g$  (where  $g$  is the acceleration of gravity and is equal to  $9.81 \text{ m/sec}^2$ ). Also, the design spectrum was used, according to Eurocode 8 [24], for soil category B and spectrum type 1. Spectrum data used according to EC8 are displayed in Table 2:

SPECTRUM DATA EC8		
N/A	Type	Data
1	Spectrum type	Horizontal design spectrum type 1
2	Soil category	B
3	Factor $\beta$	0.20
4	Seismic acceleration factor $\alpha$	For the three categories: $\alpha = 0.16, 0.24, 0.36$
5	Gravity acceleration $g$	$9.81 \text{ m/sec}^2$
6	Coefficient behavior $q$	Calculation based on EC8

Table 2: Spectrum data used for the dynamic analysis.

## 2.4 Gravity loads

The weight of the reinforced concrete is considered equal to  $25.00 \text{ kN/m}^3$ . The load of the partition masonry is considered to be evenly distributed over the entire surface of the floor plan and the load of the perimeter masonry is applied only on the perimeter beams and directly on them. Also, on the roof, all around the perimeter is considered to be a parapet with a height equal to  $0.90 \text{ m}$ . Flooring is considered to be equal to  $1.40 \text{ kN/m}^2$ . The permanent load for the masonry structures is taken equal to  $1.00 \text{ kN/m}^2$  for the internal brick structures used as partitions and equal to  $8.00 \text{ kN/m}$  for the masonry structures at the perimeter of the slab of the building. The roofing is considered equal to  $3.50 \text{ kN/m}^2$  and the load for the parapet which is at the perimeter of the roof is assumed as equal to  $3.60 \text{ kN/m}^2$ . Live loads are considered equal to  $2.00 \text{ kN/m}^2$  at every floor slab; meaning for the ground floor, the other typical floors and the roof. Permanent and live loads are shown at Table 3.

PERMANENT LOADS		
N/A	Type	Value
1	Flooring	1.40 kN/m <sup>2</sup>
2	Partition brick structures	1.00 kN/m <sup>2</sup>
3	Perimeter brick structures	8.00 kN/m
4	Roofing	3.50 kN/m <sup>2</sup>
5	Parapet roof load	3.60 kN/m <sup>2</sup>
LIVE LOADS		
N/A	Type	Value
1	Ground floor	2.00 kN/m <sup>2</sup>
2	Typical floors	2.00 kN/m <sup>2</sup>
3	Roof	2.00 kN/m <sup>2</sup>

Table 3: Permanent and live loads.

## 2.5 Modelling and dimensioning

Some assumptions were used in the design of the model of the five-storey building. Stiffness for cracked sections is considered equal to 0.5. Torsional stiffness is considered equal to 0.1. For the calculation of the masses of each floor, half the masses of the vertical structural elements of the underneath floor and half the masses of the vertical structural elements of the upper floor were used. In the context of this study, the dimensioning of the individual structural elements was carried out exclusively for the first floor (ground floor) of the five-storey building, for each of the three seismic zones. Figure 2 shows the 3D model of the building. Figure 3 displays the methodology with which the slab loads are transferred to the beams.

(a)

(b)

Figure 2: Views of the 3D building model: (a) Linear finite elements (b) Sections.

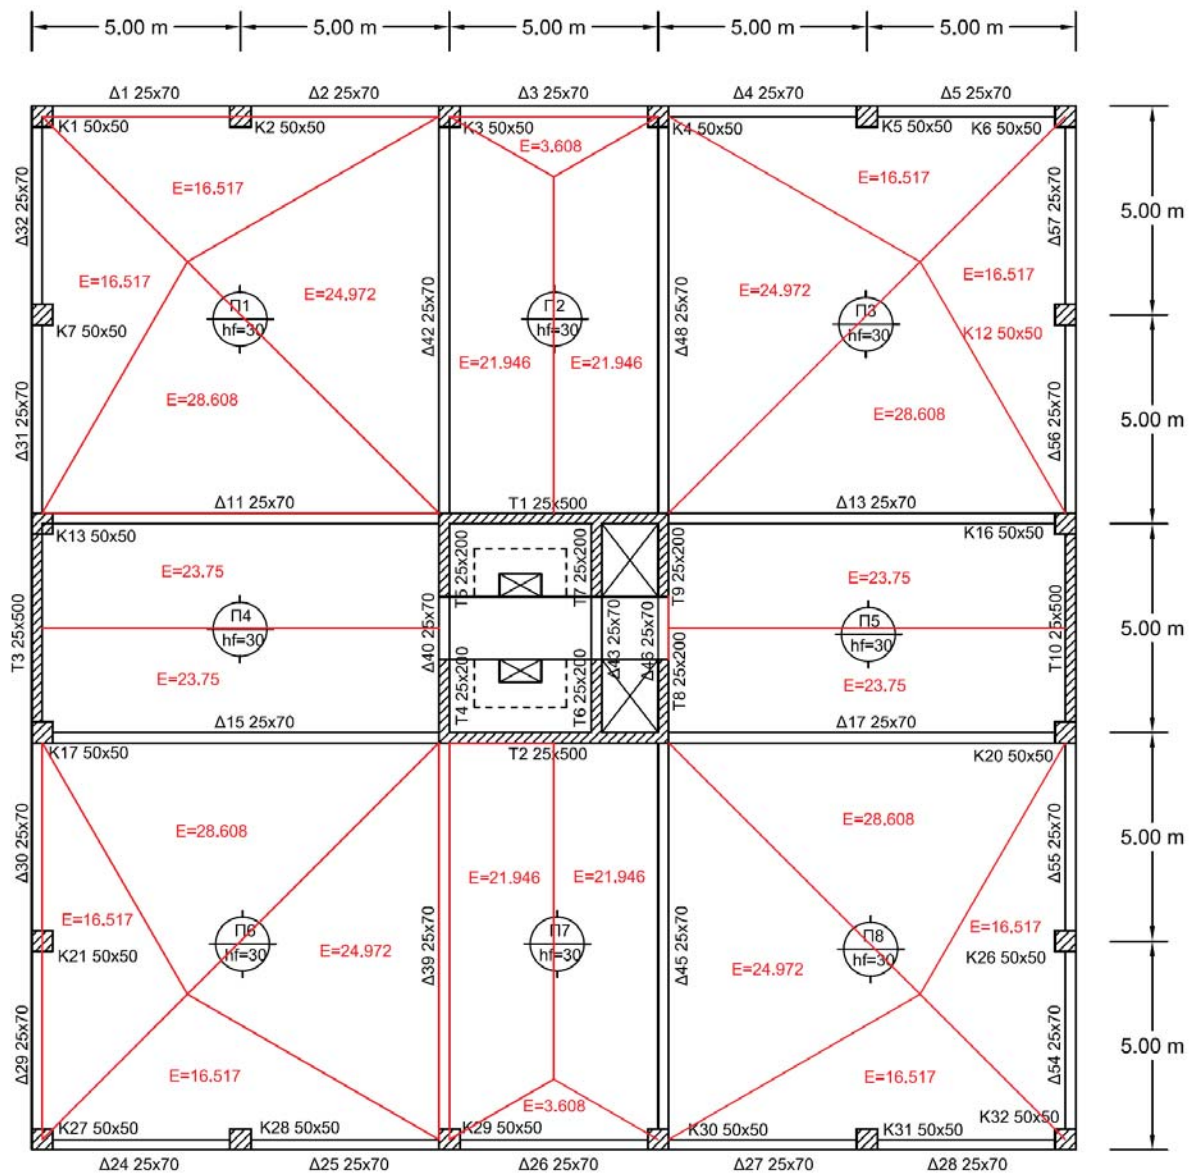

Figure 3: Methodology of calculating beam loads.

### 3 MEASUREMENTS OF MATERIALS

#### 3.1 Concrete and steel measurements for the ground floor

Concrete and steel used for the reinforcement of the structural elements are measured for the ground floor. Concrete is measured in terms of volume and reinforcement steel is measured in terms of weight. Table 4 displays the amount of concrete occupied by the structural elements of the load-bearing structure for all three seismic zones. Also, the same table displays the weight of steel used for all three seismic zones, too. Furthermore, the steel over concrete ratio is calculated and the increase of the steel weight is given in terms of percentages, again for all three seismic hazard zones.

GROUND FLOOR					
Seismic zone	Concrete volume (m <sup>3</sup> )	Steel weight (kg)	Steel / concrete ratio (kg/m <sup>3</sup> )	Increase of steel weight (%)	
Zone I	248.325	19721.91	79.42	-	
Zone II	248.325	21202.56	85.38	7.51	
Zone III	248.325	22360.64	90.05	13.38	5.46

Table 4: Concrete and steel measurements for ground floor.

### 3.2 Concrete and steel measurements for the whole building

The measurements of the materials calculated for the ground floor are used for the estimation of the quantities of the concrete and steel needed for the whole load-bearing structure of the building. Table 5 shows the results for the quantities of concrete and steel for the whole building structure.

BUILDING					
Seismic zone	Concrete volume (m <sup>3</sup> )	Steel weight (kg)	Steel / concrete ratio (kg/m <sup>3</sup> )	Increase of steel weight (%)	
Zone I	1151.58	93636.64	81.31	-	
Zone II	1151.58	99738.59	86.61	6.52	
Zone III	1151.58	105118.39	91.28	12.26	5.39

Table 5: Concrete and steel measurements for building.

## 4 ANALYSIS OF RESULTS

### 4.1 Concrete and steel measurements for the ground floor

The ratio of reinforcement steel used for the rebars over the concrete volume used for concreting the structural elements of the load-bearing structure is calculated for all three seismic hazard zones both for ground floor and for the whole building (Figure 4). Moreover, the reinforcement steel weight increment when changing seismic zone is calculated, too. This calculation takes place for changing from zone I to zone II, from zone I to zone III and from zone II to zone III both for the ground floor, as well as, for the whole building (Figure 5).

Figure 4: Steel / concrete ratio diagram for the ground floor and the whole building.

Figure 5: Diagram of steel increase when changing seismic zone for the ground floor and the whole building.

## 4.2 Analysis of results

The analysis of the previous results leads to the following:

1. As far as the floor slabs are concerned, both the volume of their concrete and the weight of their steel do not change in the three seismic hazard zones.
2. Collectively, in terms of reinforcement steel weight, there is an increase of 6.52% from seismic zone I to II and 5.39% from seismic zone II to III (Figure 5). The increase rates of the steel weight for the ground floor of the building are similar, 7.51% and 5.46% respectively (Figure 5).
3. Also, Table 5 and Figure 4 show that the requirement of the five-storey building in reinforcement in seismic zone I is 94 tn with steel to concrete ratio equal to  $81.31 \text{ kg/m}^3$ , while for zone III the weight of reinforcement reaches 105 tn with a ratio of steel to concrete equal to  $91.28 \text{ kg/m}^3$ .

## 5 CONCLUSIONS

The observation of the measurement tables of the concrete volume and those of the steel weight of the various structural elements of the building in question, as well as the tables and the various diagrams concerning the steel/concrete ratio and the percentage increase of the weight of steel leads to some conclusions that mainly concern the behavior of the structural elements but also the whole construction in the three seismic hazard zones and consequently the cost that will be spent for this construction.

1. From seismic zone I to zone II, there is an increase in seismic acceleration of 50%, from I to III 125% and from II to III 50%. These percentages should be compared mainly with the percentages of increase in the weight of steel, in order to prove if the construction cost of the building is within reasonable limits.
2. The sizing of the slabs, whether it concerns the reinforcement (steel weight) or the cross sections (volume of concrete) remains constant in all three seismic zones. Therefore, the ratio of steel to concrete in the slabs also remains constant for all floors and finally throughout the construction.
3. Regarding the whole construction, as it is logical, as the weight of the reinforcement increases separately for each structural element, moving from one seismic zone to another, the same increases for the whole construction. This change plays a very important role, as with the increase of the weight of the reinforcement, there is a corresponding increase of the cost of the structure. However, the total increase in the quantity of materials and consequently the construction cost from seismic zone I to II is only of the order of 6.52%, i.e., 8 times less than the increase in seismic acceleration in the respective zones. Also, the increase in the amount of materials from seismic zone I to III is of the order of 12.26%, i.e., 10 times less than the increase in seismic acceleration in these zones. Finally, the increase in the amount of materials from seismic zone II to III is of the order of 5.39%, i.e., 9 times smaller than the increase in seismic acceleration in the respective zones.
4. In conclusion, observing the results obtained for all the structural elements in the three seismic zones, it can be said that the rate of increase of construction costs from one zone to another is quite small in relation to the rate of increase of seismic acceleration in the respective seismic hazard zones. Thus, if the engineer wishes, for reasons of greater safety, to dimension a construction, using the immediately larger seismic zone than the one in which the construction is actually located, he can do so without significantly increasing the cost of materials (6.52% from seismic zone I to II and 5.39% from seismic zone II to III). The same could be said for the case where the building is

located in the seismic hazard zone I and the engineer wishes to dimension it in zone III. The rate of increase of the cost of materials (12.26%) is less than the safety that thus ensures the engineer for the relevant structure.

### **Abstract**

*A large portion of the civil concrete structures get damaged during an earthquake event, hence structures required some substitution and restoration. In the present study, the flexural performance of concrete beams under variation of magnitude on cyclic loading is investigated. ABAQUS finite element (FE) program is used to numerically perform a parametric study for five different depths of beams varying from 250 to 750 mm under cyclic loading. The finite element (FE) beams are modeled using Concrete Damaged Plasticity model (CDP) model. The effect of beam depth on the flexural strength of concrete beam is investigated. The effect of cyclic loading on strength and deformation behavior, yielding, ultimate, failure strengths as well as on displacements are evaluated. The load-deflection curves are obtained for different beams and are compared to static loading.*

**Keywords:** Concrete damage plasticity, Cyclic load, Finite element model, Flexural strength.

## 1 INTRODUCTION

A large portion of the civil concrete structures get damaged during an earthquake event, hence structures required some substitution and restoration. A wide range of tests have been conducted to understand the effect of cyclic load on reinforced concrete structural members during the earthquake. The failure of reinforced concrete (RC) beam is a progressive process of micro crack initiation and propagation leading to micro cracks that grow to a stage in which failure occurs. Under the repeated cyclic loading, the mechanical properties of concrete changes, thus strain increases permanently, whereas the modulus of elasticity decreases. In the case of a reinforcing bar, cyclic load causes micro- cracking that initiates a stress concentration at the bar surface. As the cyclic stress continues, the crack propagates, leading to sudden fracture crack that grow to a stage in which failure occurs.

In the present study, the flexural performance of three-dimensional nonlinear RC beams under cyclic and static loading are analyzed using concrete damaged-plasticity (CDP) [10] model available in the software ABAQUS [11].

### 1.2 Furthermore work has been done on cyclic load

Yonezawa et al., 2020 [1] investigated the effect of cyclic load on welded joints and measured the residual stress at the ultrasonic impact treatment groove using X-ray diffraction method. Ftaikhan et al., 2019 [2] studied the effect of FRP and CFRP bar embedded in RC frame subjected to dynamic loading using ABAQUS and ARCS3D finite element softwares. Tsutsumi et al., 2019 [3] analyzed the cyclic response of steel bridged pier and also evaluate the load-carrying capacity of steel bridge pier. Jamadin et al., 2019 [4] investigated the natural frequencies, mode shapes and damping ratios for bridge reinforced concrete deck slabs under cyclic and static loads. Koltsida et al., 2019 [5] tested brick masonry prisms under compressive cyclic loading at different maximum stress levels until failure and developed three mathematical equations to predict the three characteristic stages of fatigue of brick masonry. Haris and Roszevák, 2019 [6] analyzed RC frame joint under monotonic increasing quasi-static and cyclic changing loads. Xiao et al., 2018 [7] studied the effect change in loading rate on the dynamic behavior of reinforced concrete beams under cyclic loading. Harba and Abdulridha, 2017 [8] studied the effect of five different cyclic loads on RC hunched beam. Parvez and Foster, 2015 [9] showed that steel-fiber-reinforced concrete under constant amplitude cyclic loading has low smaller deflections and smaller crack widths than that of control specimens and reducing the stress level in the tensile reinforcement.

Based on the observations from the literature review and gaps, the following are the objectives of the present work:

- (i) A parametric study of five different depths of rectangular beams (having width 200 mm and length 1500 mm constant) varying from 250 to 750 mm under static and cyclic loading is carried out.
- (ii) To study the effect of increasing depth of beam on load-deflection curve of RC beams under cyclic loading and also compared it with static loading.
- (iii) To determine plastic strain, principal stress and mid span deflection under cyclic and static loadings.

## 2 PROPOSED METHODOLOGY

A rectangular RC beam having constant width 200 mm and length 1500 mm. the beam is having varying depths of 250 mm, 350 mm, 500 mm, 600 mm and 750 mm is analysed as given in Table 1. A FE element model of RC beam using C3D8 brick element has been created and analysed in FE software package ABAQUS. The material properties of RC beam are

given in Table 2. The nonlinear behavior of concrete is modeled using CDP model [10] can define the compression load behavior and tension load behavior. Figure 1 shows the cyclic loading considered in the present study having load of 2000 N to 3000 N. Figure 2 shows the FE model of RC beam. The steel reinforcement is embedded in to the concrete beam. The mesh size adopted in the present work is 50 mm.

Beam Designation	Width (mm)	Depth (mm)	Effective length (mm)	Width/Depth ratio
B-1	200	250	1500	0.8
B-2	200	350	1500	0.57
B-3	200	500	1500	0.4
B-4	200	600	1500	0.33
B-5	200	750	1500	0.27

Table 1: Beam dimensions.

Beam	Concrete mix	$f_{ck}$ (Mpa)	$f_{tk}$ (MPa)	$E_c$ (MPa)	$E_s$ (GPa)	Main Reinforcement	Stirrups	Effective cover

### 3 RESULTS AND DISCUSSIONS

Total five RC beams (B-1 to B-5) has been analyzed. The results prevail to the objectives of the study are presented and discussed in this section. Table 3 gives the initial plastic load and deflection for B-1 to B-5 beams under cyclic loading. Table 4 gives the load and deflection values under static loading of 50000 N. Figure 3 shows the load-deflection curves for B-1 to B-5 RC beams under cyclic loading. It can be observed that as the depth of beam increases the deflection decrease in the beams. Figure 4 shows the load-deflection curve for the RC beams under static loading. It can be observed from the figure that as the depth of beam increases the deflection reduces. It is observed that deflection is less in B-5 beam having a depth of 750 mm.

Beam Designation	Initial Plastic Load (N)	Initial Plastic deflection (mm)
B-1	19987.2	0.26
B-2	24932.6	0.15
B-3	29768.3	0.05
B-4	29586.4	0.03
B-5	25000	0.02

Table 3: Initial plastic load and deflection under cyclic loading.

Beam Designation	Load (N)	Deflection (mm)
B-1	50000	1.42
B-2	50000	0.70
B-3	50000	0.50
B-4	50000	0.47
B-5	50000	0.45

Figure 7: Mid span deflection for RC beams under cyclic and static loading.

Figures 5, 6 and 7 shows the plastic strain, principal stress and mid span deflection for RC beams under cyclic and static loading, respectively. The plastic strain, principal stress and deflection are observed less in the case of B-5 RC beam having a depth of 750 mm for cyclic load and static load.

#### 4 CONCLUSIONS

In the present study, the flexural performance of three-dimensional nonlinear RC beams under cyclic and static loading are analyzed using concrete damaged-plasticity (CDP) model. A parametric study of five different depths of rectangular beams (having width 200 mm and length 1500 mm constant) varying from 250 to 750 mm under static and cyclic loading is carried out. The effect of increasing depth of beam on load-deflection curve of RC beams under cyclic loading and also compared it with static loading are studied. The plastic strain, principal stress and mid span deflection under cyclic and static loadings are investigated. On the basis of FE analysis of RC beams the following conclusions are drawn:

- (i) By increasing the depth of beam that is width to depth ratio the load carrying capacity of beam increases for both cyclic and static loadings.
- (ii) In cyclic loading it is observed that as the load amplitude is high the damage observed is more as compared to static loading.

### Abstract

*The objective of this study is the development of a multilayer shell element for the nonlinear finite element analysis of reinforced concrete shear walls. The nonlinear shell element is based on a composite formulation for each integration (material) point, comprised of a number of layers with different thicknesses and material properties. For the analysis of R/C structural walls, concrete and steel nonlinear cyclic constitutive laws are assigned to each layer with isotropic plane-stress conditions for concrete and orthotropic conditions for smeared steel reinforcement, depending on their longitudinal or transverse direction. Strains at each individual layer are first derived from trial strains and curvatures of the respective integration point and then stresses are calculated by the respective layer material law. Forces and bending moments for each integration point are finally derived by numerical integration across all layers. At the present development stage, the above formulation is validated using a constitutive driver for various monotonic and cyclic strain histories, aiming eventually to its full integration into a commercial finite element code.*

## 1 INTRODUCTION

Reinforced concrete (R/C) shear walls are one of the most important lateral load resisting elements in mid- and high-rise structures, providing adequate stiffness, strength and deformation capacity, primarily against extreme earthquake and wind loading. Considering that (i) reinforced concrete is a highly nonlinear material, even under moderate loading (ii) nonlinear analysis at structural level with complex geometry is far more computationally demanding than at element level (iii) nonlinear static or dynamic (especially cyclic) loading conditions often impose convergence issues in practical applications (e.g. performance-based design or response assessment of existing structures), it is evident that providing solutions of improved accuracy, robustness and numerical efficiency for shear wall modeling is a challenging task.

In order to maintain a balance between accuracy and computational cost for nonlinear modeling of shear walls at structural level, the usual practice is to use linear elements (e.g. lumped or distributed plasticity) of equivalent section, together with rigid links or numerical constraints to provide displacement compatibility with the rest of the structure. Extending the wall element dimension to its natural planar type (e.g. membrane or shell elements), incorporating features such as plane stress conditions, out of plane response and cracking visualization, requires sophisticated element formulations and material constitutive laws. In this regard, the objective of this study is the development of a multilayer shell element for the nonlinear finite element analysis of reinforced concrete shear walls, aiming to be fully integrated into an existing commercial finite element software [1].

## 2 LITERATURE REVIEW

Over the years, a large number of numerical formulations for modeling planar R/C elements have been suggested in the literature, aiming to capture the inherent properties of concrete and steel materials under uniaxial, biaxial and triaxial stress states. From early nonlinear elasticity formulations, research has subsequently focused on plasticity and total-strain theory, fracture mechanics and (more recently) damage continuum mechanics, as well as hybrid formulations, blending more than one of the above categories. However, only a handful of the suggested solutions have managed to deploy themselves into finite element software (open source or proprietary) and therefore applied to real structural models. Reference is herein made to (i) VecTor and DIANA software, mainly including (total-strain) modified compression field theory (MCFT) [2] models, (ii) ATENA [3] software, including nonlinear elasticity as well as fracture-plasticity models, (iii) ABAQUS [4] software, with models based on damage-plasticity formulations and finally (iv) OpenSees [5], an open-source platform that accepts user contributions from the academic and engineering community. In this regard, a number of material models are available for two-dimensional modeling of shear walls, mainly based on a multilayered shell formulation, where both concrete and steel reinforcement models are attached, according to the wall section geometry. For concrete, a number of damage continuum mechanics models have been proposed, known for their simple, non-iterative formulation and computational efficiency in large, structural-level analyses: (i) the PSUMAT model by Lu et al. [6,7], using damage evolution curves under tension, as recommended by Løland [8] and under compression, as suggested by Mazars [9], (ii) the Mazars scalar elastic-damage model [9], implemented by Ramirez [10] and (iii) the two-scalar elastic-damage PRM [11] and “ $\mu$ ” [12] models, implemented by Lopez [13]. It is noted that materials (ii) and (iii) have not yet been included in the official OpenSees repository. By evaluating the performance and limitations of the above models, in the present study it was decided to adopt the layered shell formulation together with the Lu et al. concrete damage model, which has proved its numerical efficiency and robustness under large-scale structural analysis applications [6,7].

### 3 MATERIAL MODEL FORMULATION

This section describes the theoretical background and the necessary additions and modifications for integrating a nonlinear multilayer shell element into the commercial finite element software RAF [1]; a suite capable of both linear and nonlinear analysis and design of building structures, adherent to various seismic codes, including Eurocodes (e.g. [14,15]) and the Greek Code for Interventions (KANEPE) [16].

A graphical overview of a typical shear wall modeling process is depicted in Fig. 1; it comprises two boundary regions (typically 15 % of wall length each [15]) with dense longitudinal and transverse reinforcement that resist flexure and a web with two parallel grids of coarse reinforcement, designed for shear actions. These regions are usually modeled with 4-node isoparametric shell elements (MITC4), combining membrane and plate response, in order to simulate both in-plane and out-of-plane stress states. The shell mesh is characterized by a global tangent stiffness matrix ( $\mathbf{K}_T$ ) assembled by individual element contributions, while force ( $\mathbf{P}$ ) and displacement ( $\mathbf{U}$ ) vectors follow either static (Eq. 1) or dynamic (Eq. 2) equilibrium during loading.

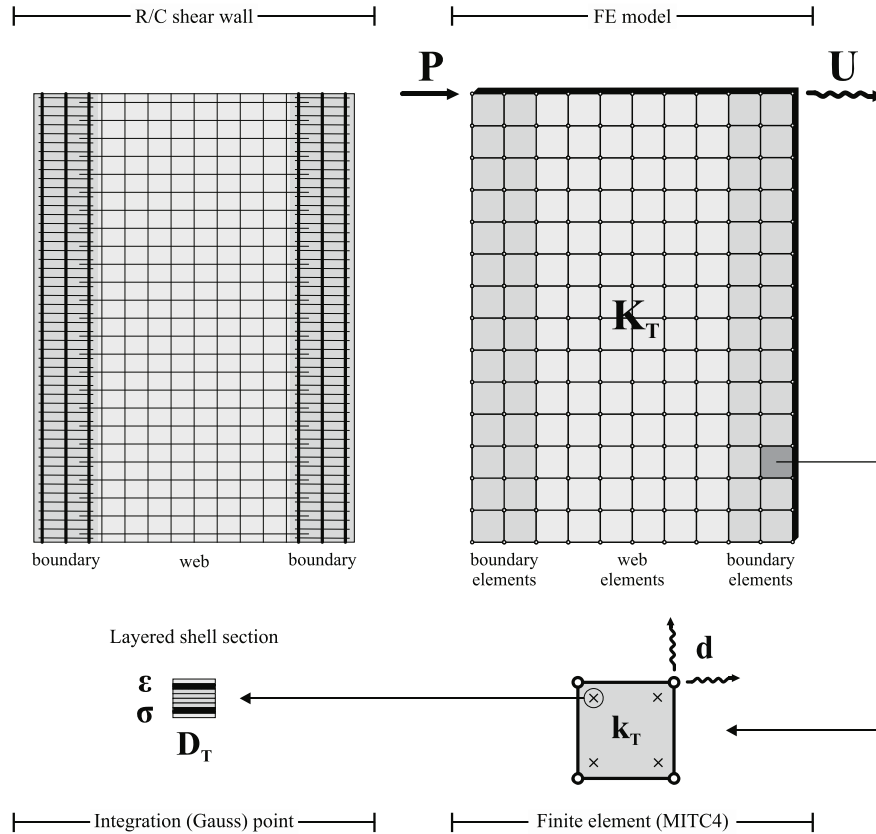

Figure 1: Overview of shear wall modeling process.

$$\mathbf{K}_T \mathbf{U} = \mathbf{P} \quad (1)$$

$$\mathbf{M} \frac{d^2 \mathbf{U}}{dt^2} + \mathbf{C} \frac{d \mathbf{U}}{dt} + \mathbf{K}_T \mathbf{U} = -\mathbf{M} \frac{d^2 \mathbf{U}_g}{dt^2} \quad (2)$$

where  $\mathbf{M}$ ,  $\mathbf{C}$  and  $\mathbf{U}_g$  are the global mass, damping and ground displacement matrices, respectively.

In the standard nonlinear finite element method, for every new load / time increment, an iterative solution algorithm (e.g. Newton-Raphson) imposes a vector of elastic trial strains ( $\boldsymbol{\varepsilon}_{tr}$ ) on each element:

$$\boldsymbol{\varepsilon}_{tr} = \mathbf{B}\mathbf{d} \quad (3)$$

where  $\mathbf{d}$  is the element nodal displacement vector and  $\mathbf{B}$  is the strain-displacement matrix. Trial strains are inserted into the nonlinear material constitutive law that updates the *material* stress vector ( $\boldsymbol{\sigma}_{n+1}$ ) and tangent stiffness matrix ( $\mathbf{D}_T$ ):

$$\boldsymbol{\sigma}_{n+1}, \mathbf{D}_T = f(\boldsymbol{\varepsilon}_{tr}, \boldsymbol{\sigma}_n) \quad (4)$$

The *element* tangent stiffness matrix ( $\mathbf{k}_T$ ) and force vector ( $\mathbf{r}$ ) are subsequently derived by integration over the element volume (using a number of integration (Gauss) points):

$$\mathbf{k}_T = \int_V \mathbf{B}^T \mathbf{D}_T \mathbf{B} dv \quad (5)$$

$$\mathbf{r} = \int_V \mathbf{B}^T \boldsymbol{\sigma}_{n+1} dv \quad (6)$$

Finally, the updated global stiffness matrix ( $\mathbf{K}_T$ ) and force vector ( $\mathbf{R}$ ) are assembled from individual element contributions.

Since the employed software [1] already features 4-node isoparametric shell elements (MITC4) for elastic analysis, the present development focuses on the inclusion of a nonlinear material constitutive law (Eq. 4) and the subsequent volume integrations (Eqs. 5-6). The material law is based on a layered shell approach [6,7] applied to each element Gauss point (Fig. 1), as is outlined in more detail in Fig. 2. Specifically, the element section is represented by a stack of ( $n$ ) individual material layers of different thicknesses ( $t_n$ ), material angles ( $\alpha_n$ ) and constitutive laws  $\{\sigma = f(\varepsilon)\}_n$ . Trial strains ( $\boldsymbol{\varepsilon}_{tr}$ ), assumed at the section midplane, are decomposed to the individual layers assuming plane-section conditions. The updated stress state for each layer is calculated by the corresponding material law and finally the updated stress state ( $\boldsymbol{\sigma}_{n+1}$ ) and tangent stiffness ( $\mathbf{D}_T$ ) for the whole section are derived using numerical integration over the total section thickness.

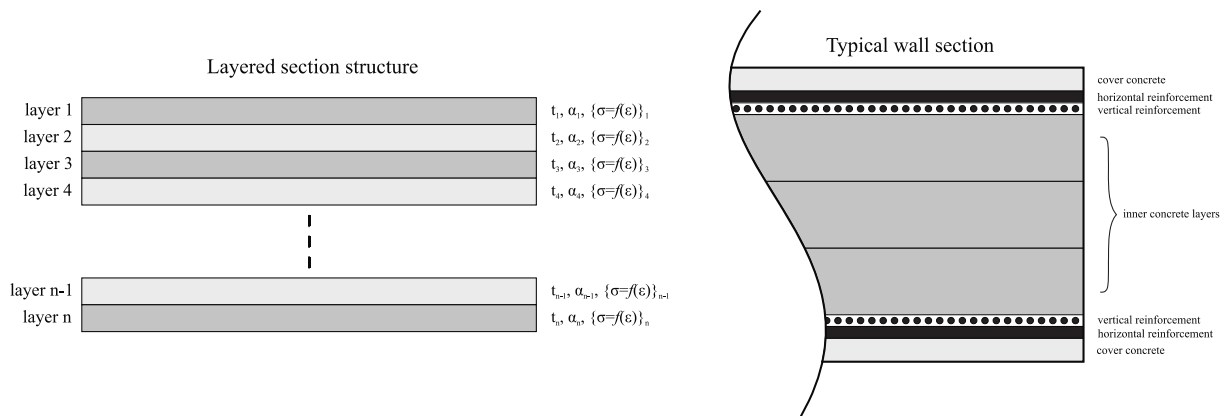

Figure 2: Layered shell formulation

In the case of a typical wall section, a layered decomposition may be simulated by two outer cover concrete layers and a number of inner concrete layers, separated by two reinforcement grids, each comprising a horizontal ( $\alpha = 0^\circ$ ) and a vertical ( $\alpha = 90^\circ$ ) smeared rein-

forcement layer. For concrete layers, the damage model by Lu et al. [6,7] is employed, with parameters derived by the characteristic concrete compressive strength ( $f_{ck}$ ), according to EN1992-1-1 [14]. For steel layers, the uniaxial Giuffr -Menegotto-Pinto model is employed [17], with parameters derived by the characteristic steel yield strength ( $f_{yk}$ ) and layer equivalent thicknesses by the corresponding steel reinforcement ratios. Fig. 3 shows the concrete, steel and layered section strain and stress states, as derived by respective constitutive laws and section integration, respectively. Eq. 7 describes the section strain decomposition to individual layers and Eq. 8 the section membrane force ( $f$ ), moment ( $m$ ) and shear force ( $q$ ) integration from layer contributions ( $z_k$  is the distance between the layer ( $k$ ) and section midplane).

Figure 3: Layer and section strain/stress states

$$\epsilon_{ij,layer\ k} = \epsilon_{ij,section} - z_k \cdot \theta_{ij,section} \quad (7)$$

$$\gamma_{ij,layer\ k} = \gamma_{ij,section}$$

$$\begin{aligned} f_{ij,section} &= \sum_{k=1}^n \sigma_{ij,layer\ k} \cdot t_k \\ m_{ij,section} &= \sum_{k=1}^n z_k \cdot \sigma_{ij,layer\ k} \cdot t_k \\ q_{ij,section} &= \sum_{k=1}^n q_{ij,layer\ k} \cdot t_k \end{aligned} \quad (8)$$

The above formulations were implemented in the form of several FORTRAN subroutines, operating on a single one-dimensional dynamic array that contains the required information (layer structure, material properties, stress states etc.) for all Gauss points corresponding to the nonlinear shell elements. Fig. 4 shows a simplified form of the developed code structure toward its integration in the commercial finite element program [1].

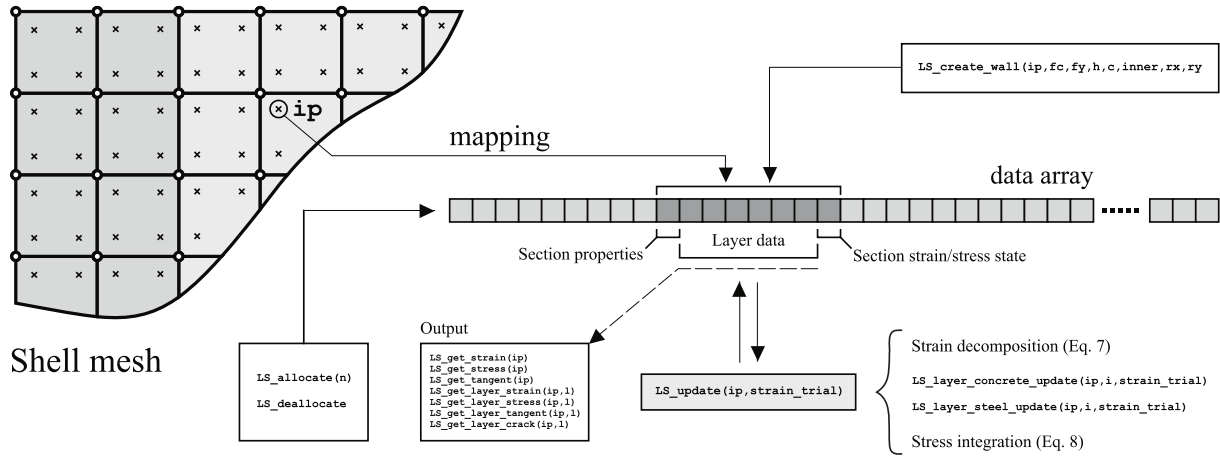

Figure 4: Simplified code structure

#### 4 VERIFICATION

Following the code development, a set of primary verification tests was performed on the material and section level, for a single element integration point. Material parameters were based on typical C20/25 ( $f_{ck} = 20$  MPa) and B500C ( $f_{yk} = 500$  MPa) concrete and steel grades, respectively, according to EN1992-1-1 [14]. Wall section width was set equal 0.2 m with three inner concrete layers, and steel reinforcement ratios equal to 5.0 ‰ and 2.0 ‰ for horizontal and vertical grid directions, respectively. Fig. 5 shows the uniaxial stress-strain response for concrete and steel layers under various monotonic and cyclic strain loading histories. It is observed that the employed constitutive models reproduce well the expected response.

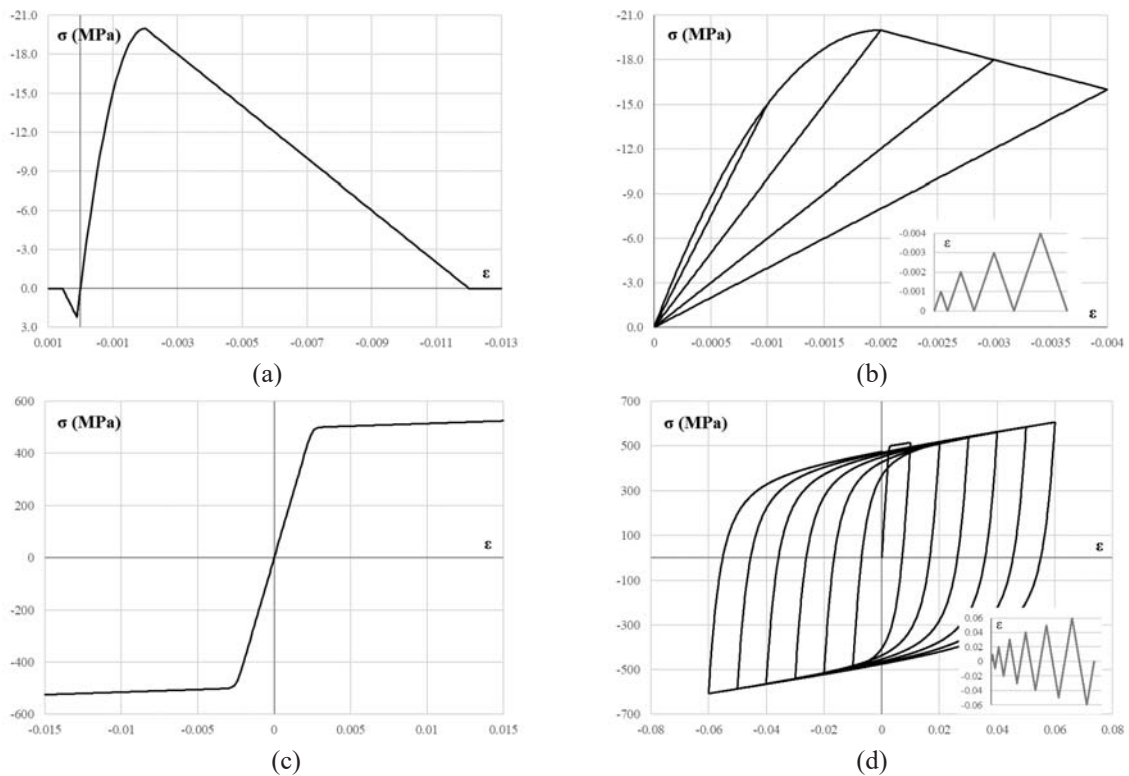

Figure 5: Uniaxial material response: (a) concrete monotonic (b) concrete cyclic (c) steel monotonic (d) steel cyclic

Fig. 6 shows the wall section response in membrane force vs. strain terms, derived by layer integration (Eq. 8) for (a) uniaxial tension in the horizontal direction followed by unloading and reloading in compression, (b) for equibiaxial compression ( $\varepsilon_1 = \varepsilon_2$ ) and (c) for compression in the vertical direction together with tension in the horizontal direction ( $\varepsilon_1 = -0.1\varepsilon_2$ ).

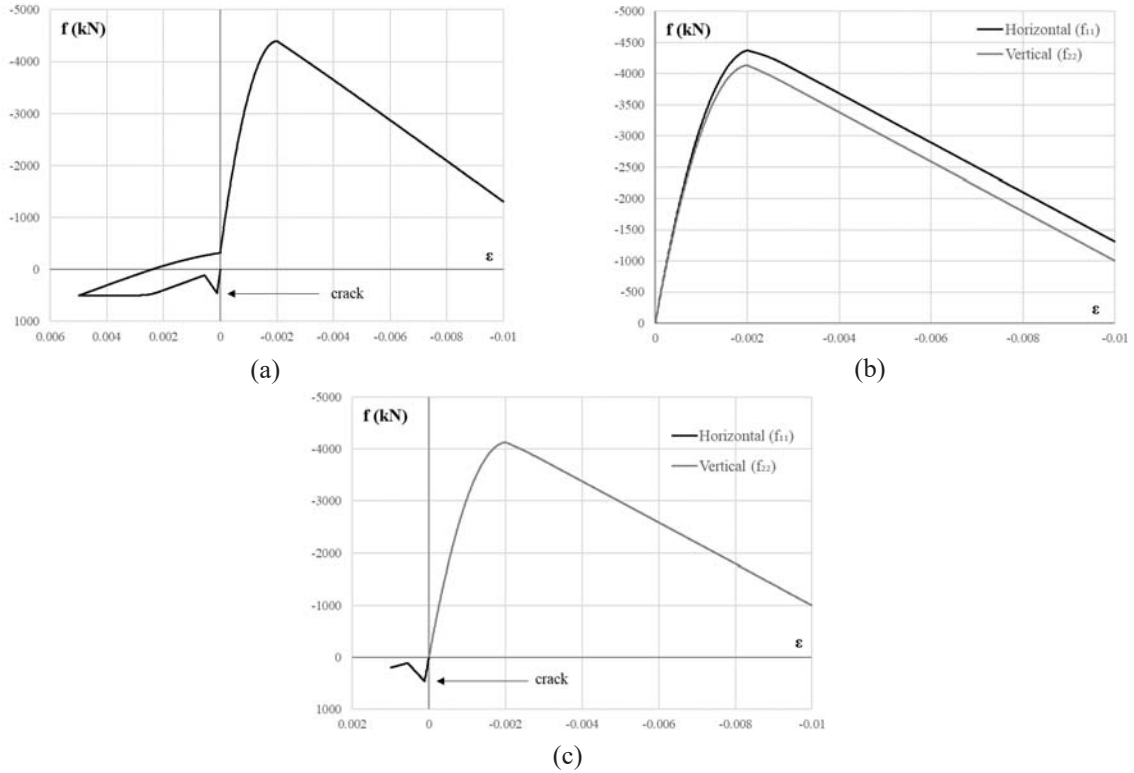

Figure 6: Membrane force vs. strain response for wall layered section

## 5 CLOSURE

In this ongoing study, a multilayer shell element for the nonlinear finite element analysis of reinforced concrete shear walls was developed, for integration into an existing commercial structural analysis software [1]. A new, modular FORTRAN-based code, operating at integration point level and based on existing formulations and inelastic constitutive models from the literature was compiled. Primary validation tests against simple loading histories at element (Gauss point) level demonstrated a satisfactory performance. This section material model will be subsequently mapped to MITC4 shell finite elements and will be further validated, for finally assembling structural models ready for nonlinear static and dynamic analysis.

## ACKNOWLEDGMENT

This research has been co-financed by the European Regional Development Fund of the European Union and Greek national funds through the Operational Program ‘Competitiveness, Entrepreneurship and Innovation’, under the call RESEARCH CREATE INNOVATE (project code: T1EDK-01800).

### Abstract

*Arches are structural forms that have been used for thousands of years and rely on gravity for their inherent stability. Currently, given the space race for lunar and martian exploration, it has become apparent that soon enough, there will be a need to design and build the first resilient shielding structures on the Moon and Mars against extreme radiation. Arches represent an ideal option for such structures given that they are durable and can be easily built. This paper is based on previous work of the authors and focuses on the stability of circular and parabolic arches with different embrace angles subjected to different levels of equivalent inertial loading in low-gravity conditions. More specifically, it reveals that although parabolic arches can be much more efficient than the corresponding circular for gravitational-only loading, this is not the case for different combinations of inertial loading and embrace angles where the opposite can be true. It highlights the dominant effect of low-gravity conditions on the minimum thickness requirements for both types of arches and considers the effect of a potential additional infill for radiation shielding. Furthermore, this study reveals a self-similar behavior and introduces a “universal” inertial loading.*

## 1 INTRODUCTION

Since ancient times, arches and vaulted structures constituted widespread structural forms, due to their inherent advantage to secure a smooth transition of the compressive internal forces from the crown to the springing. Masonry structures, were constructed during the classical period in ancient Greece. Some of those structures were vaults used as entrances to stadiums (Olympia, Nemea). Subsequently, that structural style was further advanced within the Roman period through the construction of bridges, aqueducts and tunnels [1]. In modern history, great engineers had studied the stability of arches beginning with Robert Hooke [2] who was the first to introduce the inverted chain concept with the purpose of describing the path of the compressive resultant force through a catenary (alysoid) shape. Then, Couplet [3] was the first who published his research on the evaluation of the minimum thickness of a semi-circular arch of constant thickness, subjected to its self-weight. However, for the same arch geometry, Milankovitch [4] managed to analytically calculate its minimum thickness and detect the exact locations of the hinges right after the formation of the hinge mechanism. Also, Milankovitch developed an analytical expression for the thrust line and proved that it is not an admissible catenary thrust line. Makris and Alexakis [1] not only verified Milankovitch's results, but also found out that different stereotomies can slightly affect the shape of the thrust line and thus, the minimum required thickness in order for the arch to withstand the applied loading. Additionally, based on Clemente's [5] and Oschendorf's [6] innovative research, Alexakis and Makris [7] extended their research with the evaluation of the minimum thickness of circular arches subjected to both their self-weight and horizontal acceleration that lead to a characteristic four-hinge failure mechanism.

Due to their ability to bridge long spans and their inherent strength, they are considered as suitable structural forms for creating ample space available for the storage of valuable assets or even to provide shelter to future habitable modules in extreme environments. Aiming to create a new space age, various space agencies (NASA, ESA, ISRO, etc) and private firms (SpaceX, Virgin Galactic, Blue Origin, etc) are investing in challenging missions such as "Artemis" amongst others towards the potential human settlement in other planetary bodies starting from the Moon and later on Mars. Thus, there is fertile ground for start conceptualising, designing and then, building the first extra-terrestrial habitats [8] within the coming decades. In their work Kalapodis et al., [9] present a plethora of structural concepts about the design of the prospective extra-terrestrial human habitats. The most predominant such concepts and ideas emphasise the need for an external resilient shielding structure in order to secure valuable assets (energy fuel tanks, robotic elements, future inflatable modules, etc) against harsh conditions like extreme temperature fluctuations[10] and solar radiation [11].

Such extra-terrestrial structures can be made from local soil called regolith [12] in keeping with the In-Situ Resource Utilisation (ISRU) framework [13]. This is proposed to be an arch-like structure in order to be used as storage facility and act mainly in compression since regolith, as structural material, is not expected to develop substantial tensile strength [14], while it will be able to provide the necessary compressive strength [15]. Even so, such structures will need to be durable against strong ground motions that, may be generated by shallow moonquakes [16] and marsquakes with epicentres close to the structure or generated by meteoroid impacts [17]. Since the self-weight is reduced due to the reduced gravitational acceleration (although the inertia of the structure remains constant), the structural response will change accordingly [18, 19]. This research is based on the work of [28] and deals with the limit-state analysis of both circular and parabolic monolithic arches subjected to different levels of horizontal acceleration, for regular gravity and low-gravity conditions, by assuming lower gravitational accelerations,  $a_g = \{0.17; 0.38\}g$  in accordance with the lunar and martian gravitational fields

respectively. Furthermore, a comparison of the efficiency between arches of circular and parabolic geometries is presented.

## 2 BACKGROUND OF THE PROBLEM

Except of the case of semicircular arches, various researchers dealt with the investigation of other arch geometries such as parabolic [20, 28], elliptical [21], pointed/gothic [20, 22, 23] and catenary arches [23, 24]. Most of the works mentioned above, are referred to the static behaviour and stability of the arches through determining their corresponding upper and lower bound thrust lines. According to [25], there are infinite states of equilibrium in an arch; nevertheless, the upper and lower limits for all the associated admissible thrust lines of any arch is indicated by the maximum and minimum thrust transferred to the springing (horizontal component of the reaction force) and are related to a statically determinate three-hinge arch (Fig. 1). [20] Analytically calculated the thrust line of a semicircular arch subjected to both vertical and horizontal loading. Also they proceed with the numerical estimation, through Point Collocation Method [26] and constrained optimisation, of the upper and lower limits of semicircular, parabolic and pointed (statically determinate) arches. Furthermore, [1, 4] estimated the minimum thickness of circular arches that suffices for a specific loading through limit-state analysis. Specifically, [1] confirmed the results of [4] about the dimensionless minimum thickness of semicircular arches that equals  $t/R = 0.1075$  ( $t$ : thickness,  $R$ : radius) utilising radial cuts and  $t/R = 0.1095$  by implementing vertical cuts when subjected to self-weight. The above was achieved by the calculation of the limit thrust line associated with a five-hinge mechanism (a four-hinge mechanism would not be possible due to symmetry) as shown in Fig. 2a. Subsequently, [7] determined the minimum thickness of circular arches with different embrace angles ( $\beta$ ) subjected to their self-weight combined with inertial loading. The dimensionless minimum thickness was found through a variational formulation and the application of the principle of potential energy that allowed the evaluation of the minimum horizontal acceleration levels that turn the arch into a four-hinge mechanism (Fig. 2b). Furthermore, [22] estimated the minimum dimensionless thickness of pointed/gothic arches under self-weight, on the verge of becoming a five-hinge mechanism, via the thrust-line method. After Hooke [2], the catenary shape symbolised the perfect arch shape as it represented the optimal thrust line. [24] Highlighted the deviation of the resulting thrust line from the catenary centerline of a catenary arch, although he admitted that there is no minimum thickness for a two-dimensional catenary arch under self-weight. The justification is that, as the thickness of a catenary arch tends to zero (one-dimensional arch), the thrust line tends to follow a purely catenary shape and hence, it will always be confined within the arch's geometry (intrados and extrados). The above indicates that two-dimensional arches of catenary geometry, which are subjected only to their self-weight, may constitute the best option among all the other arches of known geometries. Consequently, this work is based on [28] and aims to apply limit-state analysis to parabolic arches, since they bear great resemblance and also are more commonly used than catenary arches, for both self-weight and inertial loads. Since there is a need to provide useful observations and solid knowledge about the strength and stability of "extraterrestrial" arches serving as shielding mechanisms for valuable assets on the Moon and Mars [9, 12], the research will be applied to low-gravity fields as well. These regolith-based arches are believed to function monolithically, regardless of the construction process (additive manufacturing, interlocking bricks, etc.). Furthermore, no material shear failure (including slipping at the base) is taken into consideration, so only the development of radial cuts is permissible everywhere along the arch geometry. The impact of stereotomy is outside the reach of this paper.

Figure 1: Statically determinate semicircular arch under its self-weight, with its (a) maximum and (b) minimum thrust line.

Figure 2: Statically determinate semicircular arch under its self-weight, with its (a) maximum and (b) minimum thrust line.

Figure 3: Qualitative illustration presenting the distinctions between the symmetric five hinge mechanism of a semi-circular and a parabolic arch under self-weight. The thrust line is represented by a catenary (black dashed line) and the two optimal arches with continuous grey-scaled lines.

This study also aims to contrast the findings of the parabolic arch with those of circular arches, which are the most typical. Within Figure 3 lies the source of motivation for the qualitative identification of the failure mechanism for parabolic arches. Under self-weight only, the same thrust line (black dotted line) is marginally fitted inside both a semicircular and a parabolic (grey-scaled lines) arch with a catenary form (that bears a great resemblance to the actual thrust

lines, even though it is not an admissible one). Clearly, there are two major points to be taken from Figure 3: a) The parabolic arch's five-hinge mechanism is essentially opposite than that of the semicircular, and b) the parabolic arch is substantially thinner than the semicircular. The reference structure is a parabolic arch with an aspect ratio of  $c = 1/2$ . (as shown in Fig. 4a). Since it is closely analogous to semicircular arches, this aspect ratio is of special importance.

### 3. ANALYTICAL FORMULATION

The analytical formulation of the symmetric five-hinge mechanism owing to self-weight for the parabolic arch is presented (see Fig. 4a). One may find details about the analytical procedure and the derivation of the pertinent equations in [28] however, selective parts of the analytical procedure are presented herein for reasons of better understanding.

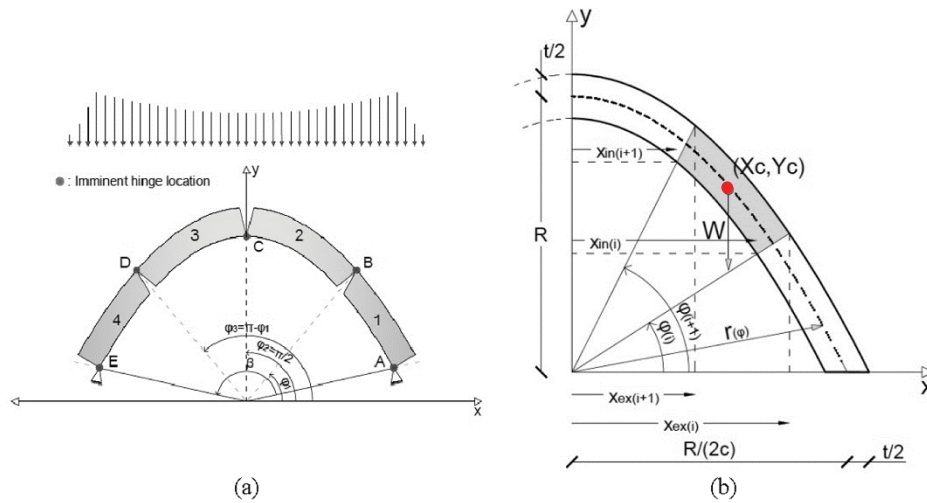

Figure 4: Parabolic arch: (a) symmetric five-hinge mechanism of the arch with  $c = 1/2$  and embrace angle  $\beta$ , when subjected to its self-weight and (b) reference system used in this study.

#### 3.1 Equations of the parabolic arch

The generic equation that describes a parabola is:

$$y = \alpha - bx^2 \quad (1)$$

The Cartesian coordinates of a parabolic arch can be represented using the following equation, assuming  $c$ : rise over span ratio (this is true only for an embrace angle of  $180^\circ$ ) and  $R$ : rise of a parabolic arch.

$$y = R - \frac{4c^2}{R}x^2 \quad (2)$$

Finally, after applying simple calculus, the Cartesian coordinates have been converted to polar and the geometry of the parabolic arch (see Fig. 4b) is expressed as follows:

$$\begin{cases} r_{(\varphi_i)} = \left\{ \frac{-\sin(\varphi_i) + \sqrt{\sin^2(\varphi_i) + 16c^2 \cos^2(\varphi_i)}}{8c^2 \cos^2(\varphi_i)} \right\} R \\ r_{(\varphi_i)} = R \end{cases} \quad \forall \varphi_i \in \left[0, \frac{\pi}{2}\right) \cup \left(\frac{\pi}{2}, \pi\right] \quad (3)$$

for  $\varphi_i = \frac{\pi}{2}$

### 3.2 Moment equilibrium at the onset of the five-hinge mechanism

The imminent hinges (at a state of equilibrium) of the collapse mechanism of the parabolic arch will appear at the intrados, where they would appear at the extrados for a semicircular arch and vice versa (Figs. 2a and 4a). The symmetric right part of the collapse mechanism is depicted in Figure 5. The gravitational multiplier,  $\alpha = \frac{g'}{g}$ , is defined as the ratio of the gravitational acceleration on other planetary surfaces,  $g'$ , over the terrestrial acceleration,  $g = 9.81 \frac{m}{s^2}$ , in order to describe different gravitational environments. Additionally, the factor,  $L = \frac{m_{total}}{m_{inertial}}$  is measured as the ratio of the structure's total mass and the additional infill mass ( $m_{total} = m_{structure} + m_{infill}$ ), over the mass that corresponds to the inertial loading ( $m_{inertial}$ ) which is a ratio of the  $m_{total}$ . For terrestrial applications where  $\alpha = 1$ , it is assumed that there is no extra infill and thus, the total mass fully participates to the inertial loads ( $m_{total} = m_{structure} = m_{inertial}$ ) and  $L = 1$ .

Figure 5: System of reference of the right symmetric part of the collapse mechanism of a parabolic arch subjected only to its self-weight.

Regarding the half right part (Fig. 5) of the arch, after applying a moment equilibrium about the point A, the minimum horizontal thrust at the intrados of the crown,  $T$ , is calculated. Considering the low gravity effect ( $\alpha$ ) and the additional vertical (shielding) loading ( $L$ ), the weight of the segment (1–2) is taken equal to  $\alpha L W_{12}$ . The moment equilibrium is represented by the following equation:

$$\begin{aligned} \text{Segment}(1-2): T \left( \left\{ R - \frac{t}{2} \right\} - \sin(\beta_0) \left\{ r_0 - \frac{t}{2} \right\} \right) - \alpha L W_{12} \left( \cos(\beta_0) \left\{ r_0 - \frac{t}{2} \right\} - x_{c12} \right) &= 0 \\ \Rightarrow T = \frac{\alpha L W_{12} \left( \cos(\beta_0) \left\{ r_0 - \frac{t}{2} \right\} - x_{c12} \right)}{\left\{ R - \frac{t}{2} \right\} - \sin(\beta_0) \left\{ r_0 - \frac{t}{2} \right\}} , \quad \beta_0 \neq \frac{\pi}{2} \end{aligned} \quad (4)$$

where:  $W_{12}$  represents the weight of half the arch

$x_{c12}$  is the abscissa of the center of gravity of the half arch

$r_0$  is the radius at an angle  $\beta_0$

After assuming a radial cut as seen in Fig. 5, moment equilibrium of the arch's upper portion (segment 2) over hinge B gives,

Segment(2):

$$\begin{aligned} -\alpha L W_2 \left( \cos(\varphi_1) \left\{ r_{(\varphi_1)} + \frac{t}{2} \right\} - x_{c2} \right) + T \left( \sin(\varphi_2) \left\{ r_{(\varphi_2)} - \frac{t}{2} \right\} - \sin(\varphi_1) \left\{ r_{(\varphi_1)} + \frac{t}{2} \right\} \right) &= 0 \\ \Rightarrow -\alpha L W_2 \left( \cos(\varphi_1) \left\{ r_{(\varphi_1)} + \frac{t}{2} \right\} - x_{c2} \right) & \\ + \frac{\alpha L W_{12} \left( \cos(\beta_0) \left\{ r_0 - \frac{t}{2} \right\} - x_{c12} \right)}{\left\{ R - \frac{t}{2} \right\} - \sin(\beta_0) \left\{ r_0 - \frac{t}{2} \right\}} \left( \left\{ R - \frac{t}{2} \right\} - \sin(\varphi_1) \left\{ r_{(\varphi_1)} + \frac{t}{2} \right\} \right) &= 0 \end{aligned} \quad (5)$$

where  $W_2$  is the weight of the segment 2

$x_{c2}$  is the abscissa of the center of gravity of the segment 2

$r_{(\varphi_1)}$  represents the radius at an angle  $\varphi_1$

As Eq. 5 is solved with respect to  $t$  (arch thickness), a transcendental equation is obtained that links the unknown rupture angle  $\varphi_1$  with the unknown minimum thickness  $t$ . The following is the general representation of this equation:

$$t = f(\varphi_1) \quad (6)$$

If adopt the horizontal axis  $x$  ( $y = 0$ ) as a level of reference, the potential energy of the parabolic arch following an embrace angle  $\beta$  (Fig. 7b) will be,

$$V = W_{arch} \cdot y_0 \quad (7)$$

where  $W_{arch}$  represents the weight of the parabolic arch and  $y_0$  is the ordinate of the center of gravity of the parabolic arch. By substituting Eq. 6 in Eq. 7, we have,

$$V(\varphi_1) = W_{arch} \cdot y_0 \quad (8)$$

Based on the theoreme of stationary potential energy, the geometrically admissible hinge mechanism (Fig. 4a) is in a state of equilibrium if and only if the total potential energy is stationary, i.e.,

$$\delta V(\varphi_1) = 0 \Rightarrow \frac{dV(\varphi_1)}{d\varphi_1} \delta\varphi_1 = 0 \Rightarrow \frac{dV(\varphi_1)}{d\varphi_1} = 0 \quad (9)$$

After solving the system of Eqs. (6) and (9) one may evaluate the unknown location of the rupture angle  $\varphi_1$  along with the minimum width  $t$  of a parabolic arch for a given embrace angle  $\beta$ .

### 3.3 Results – considering self-weight for terrestrial gravity

Figure 6 contrasts the limit thrust lines regarding semicircular and parabolic arches with embrace angle  $\beta = 180^\circ$  subjected to their self-weight. As it is expected, the collapse mechanisms are exactly opposite. Specifically, in the case of the semi-circular arch, the thrust line starts at the extrados of the base, it touches the intrados at  $35.52^\circ$  and then the extrados at the

crown, while for the parabolic arches the limit thrust line initiates at the intrados at the base, then touches the extrados at  $43.81^\circ$  and the intrados at the crown. Most importantly, the minimum thickness of parabolic arches is  $\frac{t}{R} = 0.0239$ , while the corresponding minimum thickness for semicircular arches is  $\frac{t}{R} = 0.1075$ .

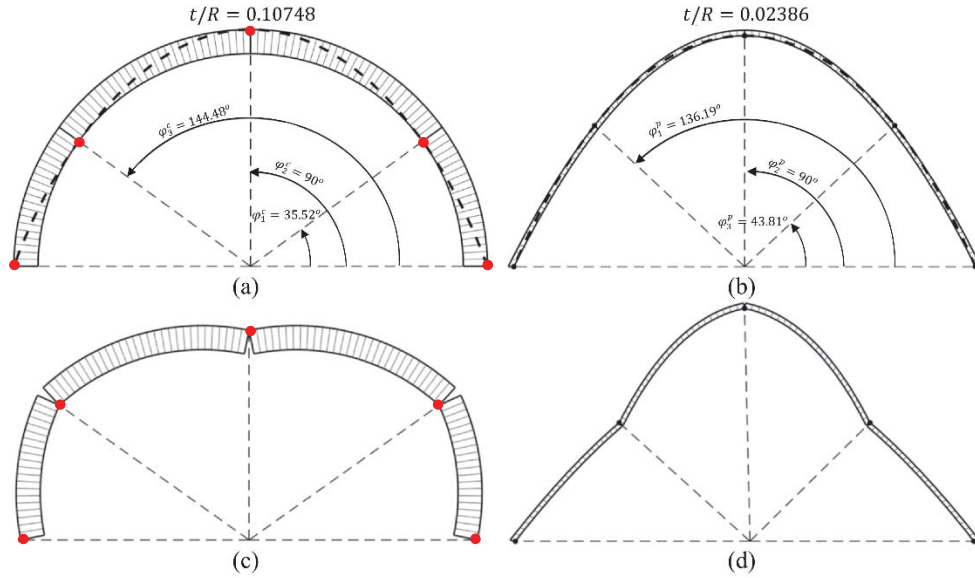

Figure 6: Limit thrust line for (a) semicircular and (b) parabolic arches; symmetric five-hinge mechanism of (c) semicircular and (d) parabolic arches when subjected to their self-weight.

Figure 7: Minimum  $t/R$  and versus various embrace angles ( $\beta$ ) for circular (solid line) and parabolic arches (dashed line) subjected only to their self-weight.

Also, figure 7 compares the minimum dimensionless thickness of circular to parabolic arches for various embrace angles,  $\beta$ . Evidently, the parabolic arches (with  $c = \frac{1}{2}$ ), always require thinner geometries to support their self-weight than their circular counterparts, regardless of  $\beta$ . Moreover, the difference between the  $\min(\frac{t}{R})$  of a circular and parabolic arch decreases for smaller values of  $\beta$  (Fig. 7).

#### 4. IDENTIFICATION OF THE FOUR-HINGE MECHANISM

When an arch is subjected to horizontal acceleration ( $\varepsilon$ ), it exhibits a four-hinge non-symmetric mechanism [7, 28]. As in the case of the five-hinge mechanism, the failure mechanisms

are exactly opposite. To facilitate comparisons between the different failure mechanisms of the two arch geometries examined in this work, the following assumptions regarding the rupture angles have been made. In the case of circular geometry,  $\varphi_1 = \varphi_1^C$ ,  $\varphi_2 = \varphi_2^C$  and  $\varphi_3 = \varphi_3^C$  while for the parabolic geometry,  $\varphi_1 = \pi - \varphi_1^P$ ,  $\varphi_2 = \pi - \varphi_2^P$  and  $\varphi_3 = \pi - \varphi_3^P$ .

#### 4.1 Moment equilibrium at the onset of the four-hinge mechanism

Following similar procedure with that of the five-hinge mechanism and after implementing moment equilibrium, one may end up to the following equation that links the lateral acceleration level ( $\varepsilon$ ) with the three rupture angles ( $\varphi_1, \varphi_2, \varphi_3$ ) and the minimum thickness ( $t$ ) [28].

$$\varepsilon = f(\varphi_1, \varphi_2, \varphi_3, t) \quad (10)$$

To calculate the rupture angles,  $\varphi_1, \varphi_2, \varphi_3$  referring to a minimum  $t/R$  and a given horizontal acceleration level,  $\varepsilon$ , the principle of potential energy is applied. Thus, the total energy of the system is expressed as the work of all forces acting on the structure with reference  $y = 0$ . The loading on a parabolic arch subjected to a horizontal acceleration,  $\varepsilon g$ , is equivalent to the gravity loading on the same parabolic arch when it is rotated by an angle,  $\omega = \tan^{-1} \frac{\varepsilon}{\alpha}$  from the vertical under a new gravitational field,  $\hat{g} = g\sqrt{\alpha^2 + \varepsilon^2}$ . The resultant gravitational field is  $\hat{g}$  and the potential energy can be expressed as

$$\begin{aligned} \hat{V} &= \hat{W} \cdot \hat{y} = \sqrt{\alpha^2 + \varepsilon^2} W \hat{y} \neq V \quad \text{or} \\ V(\varphi_1, \varphi_2, \varphi_3, \varepsilon) &= \sqrt{1 + f(\varphi_1, \varphi_2, \varphi_3, t)^2} W \hat{y} \end{aligned} \quad (11)$$

According to potential energy principle, the four-hinge mechanism is in equilibrium if, and only if, the variational work increment vanishes for arbitrary geometrically admissible variations. Therefore, the potential energy of the system needs to be stationary,  $\delta V = 0$ . The potential energy is stationary when

$$\delta V = V(\varphi_i \pm \delta \varphi_i) - V(\varphi_i) = \frac{\partial V(\varphi_i, \varepsilon)}{\partial \varphi_i} \delta \varphi_i = 0 \Rightarrow \frac{\partial V(\varphi_i, \varepsilon)}{\partial \varphi_i} = 0$$

This leads to the following expressions:

$$\frac{\partial V(\varphi_1, \varphi_2, \varphi_3, \varepsilon)}{\partial \varphi_1} = 0 \quad (12)$$

$$\frac{\partial V(\varphi_1, \varphi_2, \varphi_3, \varepsilon)}{\partial \varphi_2} = 0 \quad (13)$$

$$\frac{\partial V(\varphi_1, \varphi_2, \varphi_3, \varepsilon)}{\partial \varphi_3} = 0 \quad (14)$$

Where by substituting Eq. 11 to Eqs. 12, 13, 14

$$\frac{\partial V(\varphi_1, \varphi_2, \varphi_3, \varepsilon)}{\partial \varphi_i} = \frac{\partial f(\varphi_1, \varphi_2, \varphi_3, t)}{\partial \varphi_i} W \hat{y} \frac{f(\varphi_1, \varphi_2, \varphi_3, t)}{\sqrt{1 + f(\varphi_1, \varphi_2, \varphi_3, t)^2}} = 0 \quad i \in [1, 2, 3] \quad (15)$$

Since the horizontal acceleration is not zero,  $\varepsilon = f(\varphi_1, \varphi_2, \varphi_3, t) \neq 0$ , and that  $\hat{y}$  is nonzero as well, equation (15) yields

$$\frac{\partial f(\varphi_1, \varphi_2, \varphi_3, t)}{\partial \varphi_i} = \frac{\partial \varepsilon}{\partial \varphi_i} = 0 \quad (16)$$

Equation (10) combined with Eq. (16) for  $i \in [1, 2, 3]$  yield to a  $4 \times 4$  system of equations that can be solved in order to compute the four unknowns  $\varphi_1, \varphi_2, \varphi_3$  and  $t$  for a certain acceleration level and embrace angle  $\beta$ .

#### 4.2 Results – considering self-weight and inertial acceleration for terrestrial gravity

The minimum dimensionless thickness of the parabolic and circular arches are presented in figure 8 for terrestrial gravitational conditions ( $\alpha = 1$ ) and assuming that the whole mass contributes to inertial forces ( $L = 1$ ). As anticipated, Fig. 8 highlights i) the need for thicker geometries as the lateral inertial load increases and ii) the need for thinner geometries as the embrace angle decreases, for both the circular and parabolic case. In spite of the self-weight consideration where the parabolic arches have been proved more optimal than the corresponding circular ones, figure 8 indicates that after a certain value of embrace angle ( $\beta$ ) and lateral inertial load ( $\varepsilon g$ ), the circular arches tend to be more efficient.

Figure 8: Minimum  $\frac{t}{R}$  versus horizontal acceleration for circular and parabolic arches with embrace angles  $\{\beta = 90^\circ, 125^\circ, 155^\circ \text{ and } 180^\circ\}$ .

Figure 9 shows the different limit thrust lines for semicircular and parabolic arches under terrestrial gravity ( $g = 9.81 \frac{m}{s^2}$ ) and horizontal accelerations,  $\varepsilon g = \{0.1; 0.2; 0.4; 0.6\}g$  together with the corresponding rupture angles. Regarding the parabolic arches, given a horizontal acceleration directed from left to right, the failure mechanism always starts from the intrados at the left springing, then there is  $\varphi_1$  at the extrados,  $\varphi_2$  at the intrados and  $\varphi_3$  at the extrados of the right springing.

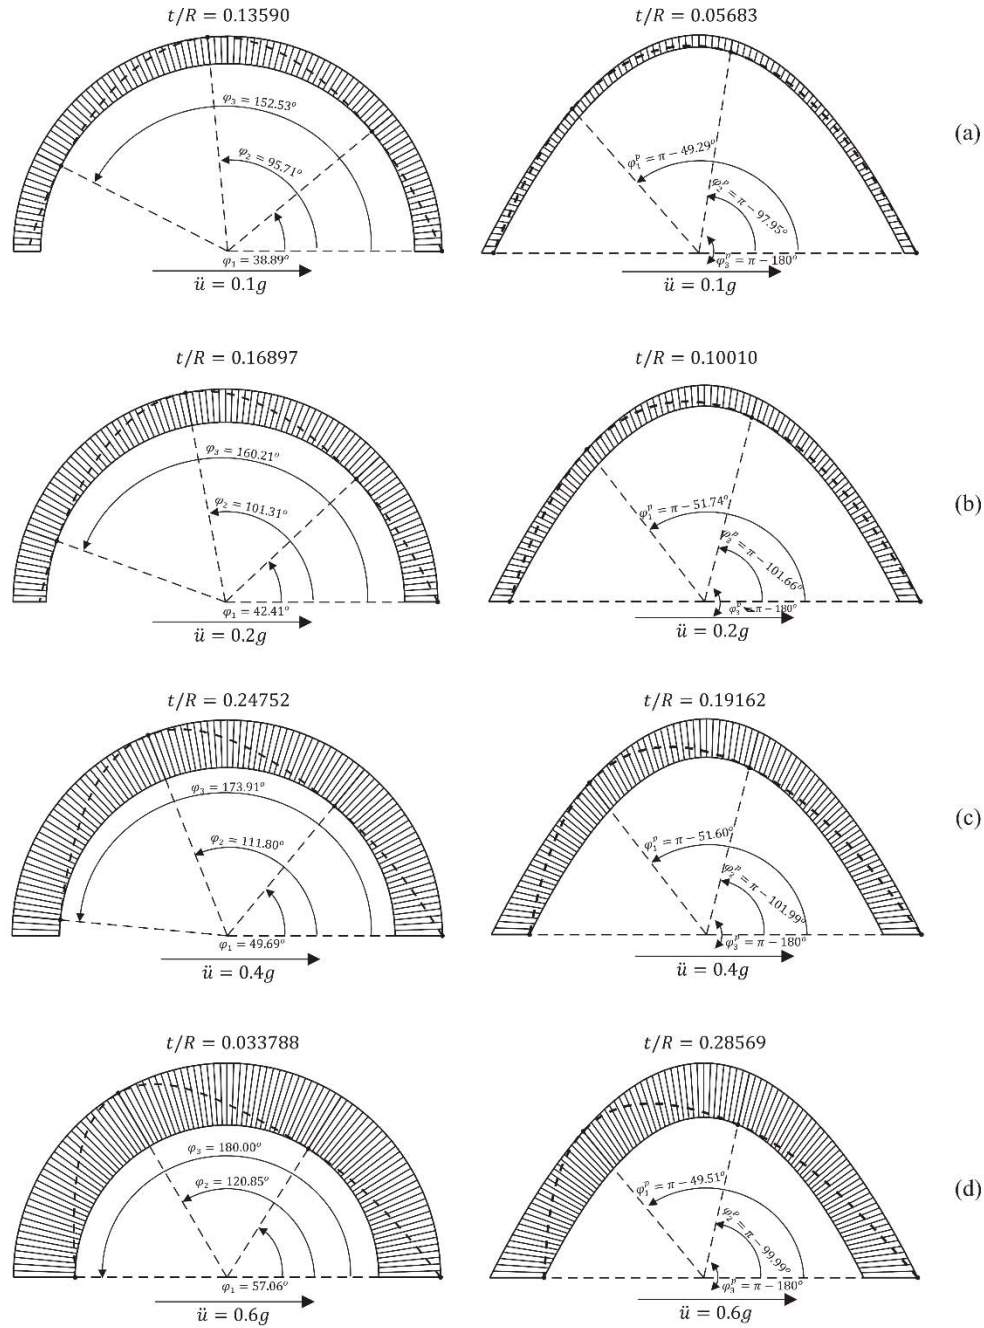

Figure 9: Contrast of the limit thrust lines for semicircular and parabolic arches under their self-weight and horizontal acceleration (from left to right) of (a)  $\varepsilon g = 0.1g$ ; (b)  $\varepsilon g = 0.2g$ ; (c)  $\varepsilon g = 0.4g$  and (d)  $\varepsilon g = 0.6g$ .

## 5. ARCHES IN LOW-GRAVITY CONDITIONS

The effects of low gravity on the stability of parabolic and circular arches are discussed in this section. The gravitational multiplier,  $\alpha = \frac{g'}{g}$ , is used to account for the influence of low gravity, with values of 0.38 and 0.17 with respect to the martian and lunar gravitational fields. Given that these arches might be used as possible shielding structures against radiation and intense temperature fluctuations, loose regolith material at the top could be needed to achieve a safe thickness of about 250 cm [27].

$L = \frac{m_{total}}{m_{inertia}} = \frac{m_{structure} + m_{infill}}{m_{inertia}}$ , in this case the factor  $L$  takes the additional mass due loose regolith infill into consideration ( $m_{infill} \neq 0$ ) and since not all of it contributes to inertial loading,  $L$  may take the values higher than 1. Specifically,  $L = 1, 2, 3, 4$  is considered herewith, where  $L = 1$  signifies that the entire mass contributes to inertia,  $m_{total} = m_{inertia}$ . Figure 10 roughly depicts the loose regolith infill atop a parabolic arch. As the structure is exposed to more regular, low-impact ground motions, (Fig. 10a), the infill remains intact (similarly to Serviceability Limit State, SLS). Thus, in this case  $L = 1$  since the infill participates entirely to the inertial loading. However, when the structure is exposed to more intense ground motions, it is highly possible that the infill will yield and then partially collapse, as it is shown in figure 10b (similarly to the Ultimate Limit State, ULS). In this case, the infill contributes only partially to the inertia of the structure, as it is not monolithically attached to it and therefore  $L > 1$ . The intensity of ground motion, the geometry of the arch, how the loose material has been connected to the arch, the coherence between the loose and the structural material, the gravitational conditions, among other considerations, all play a significant role in this partial collapse, and further analysis is required before designing such structures.

Figure 10: Minimum  $\frac{t}{R}$  versus horizontal acceleration for circular and parabolic arches with embrace angles  $\{\beta = 90^\circ, 125^\circ, 155^\circ \text{ and } 180^\circ\}$ .

Intriguingly, for both parabolic and circular arches, the phenomenon develops a self-similar behaviour portrayed by the master curves of the minimum  $\frac{t}{R}$  and rupture angles versus the dimensionless horizontal acceleration,  $\frac{\varepsilon}{\alpha L}$  in figures 11. In particular, each pair of  $\beta$  and minimum  $\frac{t}{R}$  corresponds to a unique vector of  $\left\{\frac{\varepsilon}{\alpha L}, \varphi_1, \varphi_2, \varphi_3\right\}$ . After observing figure 11 one may notice that for high values of  $\frac{\varepsilon}{\alpha L}$  (which translates to either substantial inertial loads or low-gravity conditions and no additional vertical loading) the parabolic arch is always thinner than the circular arch for  $\beta = 180^\circ$ . Nevertheless, for smaller embrace angles, there is a certain value of  $\frac{\varepsilon}{\alpha L}$  after which the circular arch becomes more efficient (in terms of material usage) than the parabolic. A more thorough investigation of the self-similar behavior phenomenon mentioned above is presented in [28].

Figure 11: Master curves of the minimum required  $\frac{t}{R}$  versus the dimensionless inertial loading,  $\frac{\epsilon}{\alpha L}$ , for both circular and parabolic arches.

## 6. CONCLUSIONS

This work is based on that of [28] and has investigated via limit-state analysis the structural behavior of circular and parabolic arches when they are subjected to self-weight, additional vertical weight and inertial loading in low-gravity conditions. More specifically, this research uses a variational formulation to evaluate the minimum necessary thickness of the various arches in order for them to avoid becoming a mechanism under various load combinations and gravitational fields. The findings indicate that contrary to circular arches, parabolic arches need a far lower minimum thickness to withstand their own weight and display the symmetrically opposite five-hinge mechanism. This manifests the “geometrical superiority” among structures that resemble the catenary shape (parabolic) under self-weight. It is observed that larger inertial loading results in higher minimum thickness, smaller embrace angles lead to thinner arches.

Interestingly, both the symmetrical five hinge mechanism formed due to the effect of self-weight and the asymmetrical four-hinge mechanism developed due to the horizontal loading are opposite for the two types of arches. Nevertheless, regarding the four-hinge mechanism, the mechanism pattern shows a significant similarity between these two arch geometries, in the sense that as the inertial loading increases, in all cases, the mechanism tends to move “upstream” against the horizontal load in order for the arches to accommodate their limit thrust lines.

Moreover, a self-similar behaviour has been observed, revealing that every arch of a certain geometry type and embrace angle ( $\beta$ ) that is subjected to a “universal” dimensionless inertial load  $\frac{\epsilon}{\alpha L}$ , always results in the same minimum thickness and rupture angles  $\{\frac{t}{R}, \varphi_1, \varphi_2, \varphi_3\}$ . One may refer to [28] for further information about the analytical procedure, the justification of the self-similarity and the conditions under which the parabolic geometry is more efficient than the corresponding circular and vice versa.

Given all the above, the need to optimise the arch geometry becomes apparent in low-gravity conditions, as shown in Section 5, since the required minimum thickness can become prohibitively large.

**Abstract.** *Unreinforced masonry (URM) has been the most widespread construction material for centuries and is widely used in many countries. Accurate numerical models for this material are required when designing new structures, and, even more importantly, for assessing or renovating the existing stock. However, an accurate modelling of URM structures remains a challenge due to its highly non-linear mechanical behaviour involving, among other features, large out-of-plane displacements, the variability of the material properties, and the influence of construction details. The discrete element method (DEM), for which applications to masonry structures appeared in the 1990s, has gained in popularity due to its capacity to accurately capture masonry-specific phenomena; in particular, as it represents the structure as an assembly of distinct blocks, deformations are concentrated at the interfaces with low or zero tension strength, and the effect of large displacements. Unfortunately, the majority of computer programs for structural analysis based on the DEM are proprietary software, which limits its spread among practitioners and researchers. The aim of this work is to evaluate the open-source software package LMGC90, which implements the Non-Smooth Contact Dynamics Method, as a tool for modelling masonry structures.*

## 1 INTRODUCTION

Recently, the region of Wallonia (Belgium), along with the neighbouring parts of France, Germany and Holland, was indicated as one of the locations in Europe with potential for largest economic losses, because of their very large exposure and vulnerability to earthquakes [3]. Recent exposure studies have shown that the most earthquake-prone cities in Belgium have an absolutely predominant stock of URM buildings [4, 13]. One example is the city of Liège - struck by an earthquake in 1983 damaging around 16'000 houses - for which 95% of their buildings are in masonry [2]. A good understanding of the structural behaviour of typical Belgian masonry houses is therefore required to predict and best prevent the occurrence of potential damage in future low- to medium-intensity earthquakes.

In this paper, we investigate the open source software *LMGC90* [12] as a tool for modeling masonry structures subjected to earthquakes. This software was originally developed for spherical elements, simulating rapid granular flows [14]. Eventually, it was adapted to polyhedral elements and its relevance for URM modeling has been growing ever since [11]. This software has been used to study the seismic behaviour of historical masonry structures such as the Roman amphitheatre in Nîmes [15], a medieval church in Portuno [10], or the reassessment of a wall in the Prince of Wales's Fort [9]. In the last decade, some specific features relative to the modeling of URM buildings have been added to *LMGC90* and the software becomes more and more interesting for the URM community [16]. The aim of this paper is to evaluate the suitability of the software for masonry modeling. The results of the examples presented in the current study are benchmarked against analytical solutions and numerical results obtained with another well-known proprietary DEM software, namely *UDEC* [5, 6]. The examples presented in this study address several issues encountered when modeling the large-displacement response of masonry structures subjected to earthquakes, like the effect of rocking, contact stiffness and imperfections between the blocks. Two benchmark problems are presented and discussed in this paper. the first one addresses the rocking response of masonry columns, and the second one addresses the in-plane behaviour of masonry panels. In Section 2, a masonry column and a masonry arch are submitted to a horizontal impulse acceleration at the base and the failure domain is computed in terms of impulse amplitude and duration. The results are compared with those of a *UDEC* model reported in the literature [7]. In Section 3, the in-plane behaviour of a series of panels is analysed through up-to-collapse quasi-static simulations. The results are shown in terms of collapse mechanism and force capacity for each wall and compared with existing solutions extracted from the literature [8] as well as with the results of ad-hoc *UDEC* simulations.

## 2 RESPONSE OF COLUMNS AND ARCHES TO IMPULSE BASE ACCELERATION

### 2.1 Description of the benchmark

The aim of this benchmark is to explore the ability of *LMGC90* to capture the rocking mechanism of masonry structures. Moreover, the construction of non-convex shapes — with the associated difficulties of contact determination — is addressed in the second part of the example.

Firstly, the dynamic behaviour of a URM column (dimensions shown in Figure 1a) subjected to a two-sided horizontal base impulse acceleration represented in Figure 2 is analysed. A parametric study is carried out on the column by increasing the acceleration amplitude  $a$  for a range of impulse duration  $t_p$  varying between 0.1 and 1.0 s. This is done in order to obtain the failure domain of the column, i.e. the couples of values  $(a, t_p)$  which lead to the collapse of the column. The column modelled in this example is inspired from the 9<sup>th</sup> column of the eastern

Figure 1: Geometry of the analysed column (a) and arch (b)

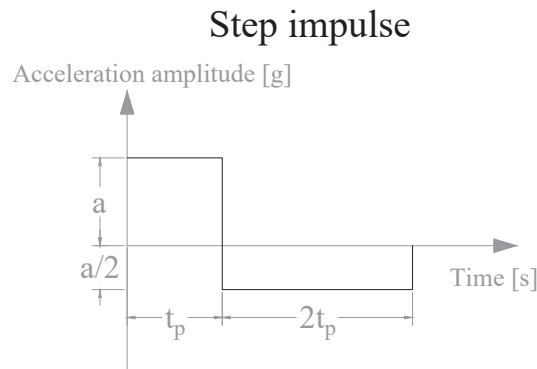

Figure 2: Acceleration step impulse applied to the base of the column [7]

flank of the temple of Apollo at Bassae, Greece. It is composed of 8 drums and has a total height of 5.95 m, a base width of 1.11 m and a top width of 0.9 m. The model implemented in *LMGC90* is in two dimensions with rigid blocks with a density of  $2620 \text{ kg/m}^3$ . The contact between the blocks is a Coulomb friction law with a friction angle of  $35^\circ$ , which is equivalent to a coefficient of friction  $\mu = 0.7$ . The simulation is run for 20 s in order to observe the response of the column after the application of the step impulse. The failure domain obtained with this model is compared with the one obtained by the implementation of the same problem using UDEC, by Dimitri et al. [7]. The *UDEC* model is implemented without damping while the damping model used in *LMGC90* is the default model of the program. The definition of the damping model and damping parameters in *LMGC90* will be explored in future studies.

A similar study is then carried out for a circular arch supported on buttresses. The dimen-

sions of the problem are shown in Figure 1b. The arch consists of 12 voussoirs, while each buttress is modelled as one monolithic block. The base of the buttresses is subjected to the same two-sided impulse acceleration used in the previous example. In particular, the acceleration is progressively increased until the failure of the arch is attained. Moreover, the position of the hinges that form in the collapse mechanism at specific values of  $a$  and  $t_p$  is compared with the results obtained with UDEC [7].

## 2.2 Results and discussion

The results obtained with *LMGC90* are summarised in this section. The plots were generated with the open-source multiple-platform application for interactive scientific visualisation *ParaView* [1].

Figure 3a shows that the failure domain obtained with the model implemented in *LMGC90* agrees well with the failure domain obtained with *UDEC* in the work by Dimitri et al. [7]. As the value of  $t_p$  increases, the acceleration amplitude causing the collapse of the column comes closer to the value of 0.19g, which is the magnitude necessary to put the column in motion according to the equilibrium static analysis. Acceleration amplitudes below that value are not going to initiate any rocking or sliding of the column [7]. The graph also hints at a change in the failure mode at around  $t_p = 0.34$ s: below that value, the columns tilts to the left and only a portion of the blocks is involved in the failure mechanism, whereas the full column tilts to the right for impulse duration above this threshold value. The failure modes obtained at  $t_p = 0.2$ s and  $t_p = 0.8$ s are displayed in Figures 3b and 3c. This could be explained by the fact that, below this threshold value, the column collapses during the first part of the impulse (positive acceleration  $a$ ) whereas for longer impulses the collapse occurs in the second part of the impulse (negative acceleration  $a/2$ ). In addition, for shorter impulses, higher rocking 'modes' are activated. As the impulse duration decreases, the results from *LMGC90* and from Dimitri et al. [7] seem to match a little bit less. This difference is probably due to definition of the damping parameters in *LMGC90*, which will be analysed in future studies.

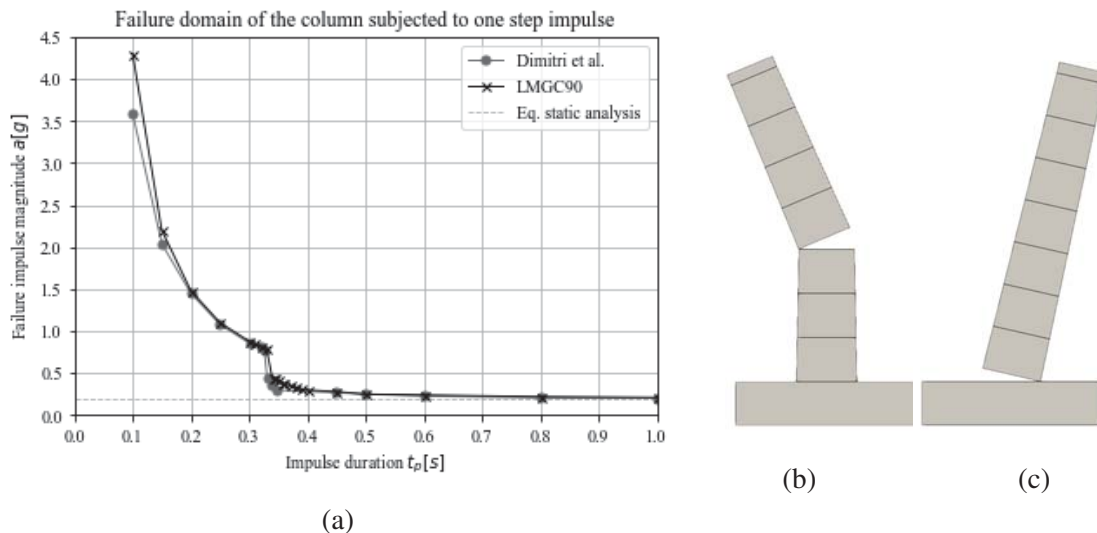

Figure 3: (a) Failure domain of the column subjected to the step impulse (b) Failure mode at  $t_p=0.2$ s and (c) Failure mode at  $t_p=0.8$ s

Figure 4 shows the results obtained for the arch of Figure 1b. Also in this case the results

obtained with *LMGC90* match very satisfactorily those obtained by Dimitri et al. [7]. Moreover, the collapse mechanisms produced by both software at two different acceleration amplitudes were compared and are in good agreement in terms of the position and number of hinges that form at collapse, see Figures 6a and 6b.

### 3 IN-PLANE BEHAVIOUR OF MASONRY WALLS SUBJECTED TO STATIC LATERAL LOAD

#### 3.1 Description of the benchmark

In this benchmark, quasi-static analyses are performed on a series of six wall configurations. Each wall is composed of bricks of size  $0.4\text{ m} \times 0.175\text{ m}$  with sharp or rounded edges, as depicted in Figure 7. The walls have different geometries, four of which include openings, as depicted in Figures 8 to 13. During the analysis, each block is subjected to its self-weight  $W$ , being the unit weight of the blocks equal to  $10\text{ kN/m}^3$ , and to a horizontal force  $\alpha W$  applied at its centre of gravity (Figure 7a). This configuration allows the seismic loading to be simulated as an equivalent static lateral force distribution proportional to the blocks mass [8].

Figure 7: (a) Block and half-block with sharp edges (applied forces shown on the full block) for comparison with [8] (b) Block and half-block with rounded edges for comparison with *UDEC*

The objective of this example is to find the maximal in-plane capacity of the wall, which, according to the load pattern described above, is expressed in terms of maximum collapse load multiplier  $\alpha_{max}$  and corresponds to the maximum value of  $\alpha$  that the wall can sustain.

### 3.2 Comparison between solutions from limit analysis and *LMGC90*

First, the benchmark is implemented in *LMGC90* with rigid blocks with sharp edges as shown in Figure 7a. The contact law between the blocks is defined by a rigid-plastic law, and failure between the blocks is described by a Coulomb friction criterion with friction coefficient  $\mu=0.65$  and zero tensile strength. During the first 10 s of the simulation, the bricks are only subjected to their self-weight. Next, the value of the load multiplier  $\alpha$  is linearly increased at a rate of  $5 \times 10^{-4}/s$  which is assumed to be low enough to keep the system in quasi-static conditions until the collapse mechanism forms. The value of  $\alpha_{max}$  selected as the collapse load multiplier is the maximal horizontal reaction observed at the support divided by the total weight of the wall. Indeed, a decrease in the horizontal reaction while the total applied horizontal force keeps increasing linearly can only mean that equilibrium is no longer satisfied and that part of the applied horizontal force is converted into kinetic energy.

Figure 8: Mechanism of wall 1 (sharp edges) from limit analysis [8] (left) and *LMGC90* (right)

Figure 9: Mechanism of wall 2 (sharp edges) from limit analysis [8] (left) and *LMGC90* (right)

Figure 10: Mechanism of wall 3 (sharp edges) from limit analysis [8] (left) and *LMGC90* (right)

Figure 11: Mechanism of wall 4 (sharp edges) from limit analysis [8] (left) and *LMGC90* (right)

Figure 12: Mechanism of wall 5 (sharp edges) from limit analysis [8] (left) and *LMGC90* (right)

The values of  $\alpha_{max}$  are compared with the collapse load multipliers calculated by means of a limit analysis of the walls formulated as a special optimisation problem known as Mathematical Program with Equilibrium Constraints (MPEC) described by Ferris and Tin-Loi [8]. The results are summarized in Table 1. The collapse mechanisms obtained with *LMGC90* are compared with those shown by Ferris and Tin-Loi [8] in Figures 8 to 13. The figures obtained by *LMGC90* are plotted when the displacement of the upper right corner of the wall was equal to 0.2m. The value of this displacement is not specified in [8] but the figures clearly display very similar cracking patterns.

	$\alpha_{max}$ Sharp edges		% Error
	Ferris [8]	<i>LMGC90</i>	
Wall 1	0.643	0.640	-0.5
Wall 2	0.564	0.565	+0.2
Wall 3	0.359	0.358	+0.3
Wall 4	0.264	0.266	+0.8
Wall 5	0.216	0.216	+0.0
Wall 6	0.297	0.295	-0.7

Table 1: Collapse load multipliers computed in [8] and with *LMGC90*

The results obtained with *LMGC90* are very close to the ones obtained by limit analysis [8], both in terms of collapse load multiplier (with a maximal difference of 0.8%) and in terms of

Figure 13: Mechanism of wall 6 (sharp edges) from limit analysis [8] (left) and *LMGC90* (right)

collapse mechanism.

### 3.3 Comparison between solutions from *UDEC* and *LMGC90*

Since neither the limit analysis carried out by Ferris and Tin-Loi [8], neither the *LMGC90* implementation described above take into account any axial stiffness of the bed and head joints, the deformations of the wall before reaching collapse will be zero. Another model has been implemented in two different DEM software, the proprietary software *UDEC* and the aforementioned open source software *LMGC90*. This was also done in order to consider the effect of imperfections in the brick corners. This is assumed to be closer to reality than the implementation in section 3.2 where contact was perfectly plastic and blocks had sharp corners.

The bricks implemented in both software are rigid, 2D and have the same dimensions as previously but this time the corners are rounded with a rounding radius  $r_b$  of 0.02 m, as shown in Figure 7b. Moreover, the contact law is different than in Section 3.2 in order to take into account the stiffness of the joints. In *UDEC*, the user can define the friction coefficient between the blocks ( $\mu = 0.65$ , as previously), the normal stiffness which was set to  $k_n = 10^8$  Pa/m, the dilatancy angle and the tangential stiffness. Regarding the two latter parameters, since *LMGC90* does not allow to define a tangential stiffness nor a dilatancy angle, those parameters have been set to a very high value and to zero, respectively, to allow a valid comparison with the model implemented in *LMGC90*. Therefore, in the *UDEC* model  $k_t = 10^{14}$  Pa/m and  $\psi = 0^\circ$ . Since the axial stiffness parameter  $K_n$  defined in *LMGC90* must be expressed in N/m, the contact stiffness from the model implemented in *UDEC* must be multiplied by the surface associated to each contact point, namely  $0.1m^2$  for the bed joints (4 contact points for each brick's bed joint) and  $0.0875m^2$  for the head joints (2 contact points for each brick's head joint).

Table 2 summarises the results obtained for the six walls with rounded blocks, both with *UDEC* and *LMGC90*. The collapse load multiplier of the walls with rounded edges is a little lower than its equivalent with sharp edges.

	$\alpha_{max}$		% Error	Sharp edges [8]	% Difference between sharp and rounded edges
	UDEC	LMGC90			
Wall 1	0.577	0.578	+0.2	0.643	-10.1
Wall 2	0.495	0.512	+3.46	0.564	-9.2
Wall 3	0.325	0.321	-1.24	0.359	-10.6
Wall 4	0.236	0.242	+2.7	0.264	-8.3
Wall 5	0.157	0.175	+11.2	0.216	-19
Wall 6	0.219	0.216	+1.6	0.297	-27.2

Table 2: Collapse load multipliers computed with *UDEC* and *LMGC90*Figure 14: Mechanism of wall 1 (rounded edges) from *UDEC* (left) and *LMGC90* (right)Figure 15: Mechanism of wall 2 (rounded edges) from *UDEC* (left) and *LMGC90*Figure 16: Mechanism of wall 3 (rounded edges) from *UDEC* (left) and *LMGC90*

Figure 17: Mechanism of wall 4 (rounded edges) from *UDEC* (left) and *LMGC90*

Figure 18: Mechanism of wall 5 (rounded edges) from *UDEC* (left) and *LMGC90*

Figure 19: Mechanism of wall 6 (rounded edges) from *UDEC* (left) and *LMGC90*

The collapse mechanisms of the six walls with rounded edges are displayed in Figures 14 to 19. Both for *UDEC* and *LMGC90*, the collapse mechanism is displayed when the upper right corner of the upper right brick reaches a displacement of 0.2 m. In general, the two solutions are very close to each other in terms of collapse mechanisms. The exception is in the mechanism

of the third wall, where a bigger macro-block detaches from the structure in the mechanism obtained in *UDEC*, see Figure 16.

The values of the collapse load multipliers obtained with *LMGC90* are always higher than the values obtained with *UDEC* with a maximal error right above 10% for the fifth wall, with the exception of the third wall, which can be explained by the difference in the collapse mechanisms. When comparing the full displacement - load factor curves (not represented herein), the results obtained with *LMGC90* always seem to indicate that the walls are slightly stiffer than in *UDEC*, except for the stiffness in the elastic range which is identical in both software. This difference in stiffness, which could be a consequence of the distinct definition of the normal stiffness discussed above, could explain why the collapse load multipliers obtained with *LMGC90* are always higher than the ones obtained with *UDEC*. This matter will be explored in future works.

The comparison between both software is still limited by the impossibility in *LMGC90* to use a contact law between the blocks that includes parameters such as dilatancy or tangential stiffness, which are very common when working with *UDEC*. Inversely, the impossibility to define sharp edges when using *UDEC* makes it difficult to compare the results obtained with this software with the limit analysis carried out in [8].

## 4 CONCLUSION

Different benchmark problems have been implemented in the open-source DEM software *LMGC90* and the results were compared with the literature or with an implementation of the same benchmark problem in the proprietary software *UDEC*. These examples were chosen in order to address some of the most important aspects such as rocking, the joint stiffness and the block imperfections. Overall, the results obtained with the open-source software showed satisfactory resemblance with the literature and with the implementations in *UDEC*. Familiarisation with the interface of *LMGC90* can be time-consuming, and the choice of the tolerance and time step parameters of a simulation requires some experience, but once the user is familiar with the Python interface proposed by *LMGC90* and with the structure of the software, it opens up many possibilities for either static or dynamic analyses. The results shown in this paper confirm the applicability and validity of this open-source software in simulating large-displacement response of masonry structures. Future investigations into the possibilities offered by the *LMGC90* software regarding modeling of URM could include in-and-out-of-plane interaction of masonry walls, definition of more parameters such as dilatancy, tangential contact stiffness and damping.

### Abstract

Column base connections are one of the most critical components in Steel Moment Frames (SMFs) since these connections transfer the loads (i.e., gravity, seismic, wind) from the entire superstructure into the concrete-foundation, being an interface between them. Typically, exposed base plates are preferred for low-and mid-rise buildings, while embedded base connections are the norm for tall buildings. This latter base configuration response is controlled by complex interactions between the column flange and the bottom base plate with the concrete foundation, where the mechanisms to transfer internal forces are idealized to underpin the current strength design methods. These mechanisms include horizontal bearing stresses between the column flange and the surrounding concrete and vertical bearing stresses of the base plate and the concrete foundation. Current methods to estimate the strength of these connections are validated against a limited number of experimental tests complicating their generalization for the different configurations that have not been tested. Although the results from these methods show good agreement with test data, the assumptions that underpin these methods have not been verified through sophisticated nonlinear finite element models. Motivated by this issue, this paper presents a series of nonlinear finite element models developed to provide insights into the behavior of embedded base connections for SMFs. These models incorporate the essential aspects that control the connection behavior, including constitutive material modeling and contacts among the connection components. Possible design implications are discussed, while the limitations of the current work and future lines of research are outlined.

---

## 1 INTRODUCTION

Column Base Connections are one of the most important components of Steel Moment Frames (SMFs). Several researchers [1-6] have demonstrated their significant influence on the seismic performance of SMFs systems. Because of this, these connections have been extensively studied over the last decade in different programs [7-11]. Typically, base connections can be broadly classified as exposed base plates (EBPs) and embedded base connections (EmBCs). The former type is the preferred detail for low to mid-rise buildings, while the latter is the norm for tall buildings.

EmBCs consist of a column welded to a bottom base plate (Refer to Fig. 1) and embedded into a concrete foundation. The applied forces, i.e., Axial Load, Bending Moment, and Shear, are resisted by a combination of the bearing stresses developed by the contact between the column flange and the foundation and by the vertical stresses at the bottom base plate. Grilli and Kanvinde [7] conducted a large-scale experimental program to study the seismic response of EmBCs. This program's focus was the flexural capacity of these connections and the development of a strength method based on the insights gained from the tests. A total of five tests were evaluated. The difference among them was the embedded length (510 and 760mm), column size, and axial load level.

Grilli and Kanvinde [7] postulated an internal stress distribution to idealize the mechanism that resists the applied loads. Figure 1 illustrates this mechanism which consists of horizontal bearing stresses accompanied by joint shear in the panel zone and vertical stresses at the bottom base plate. However, this idealized mechanism relies on pre-defined stress distribution (rectangular) on the bottom base plate as well as in the column flange against the foundation. It is well-known that the real stress distribution might differ from the assumed one due to the complex interactions between the components.

The behavior of EmBCs has been studied in the past from different perspectives. Grilli and Kanvinde [7] suggested a strength method to estimate their flexural strength. Torres-Rodas [12] proposed a procedure to estimate their rotational stiffness by aggregating the deformations within the components. The hysteretic characteristics of these connections were explored by Torres-Rodas [13] through a hinged model, which was validated experimentally and capture the force transfer mechanisms observed at [7]. Recently, Inamasu et al., [14] developed Finite Element (FE) models to explore the behavior of EmBCs further and suggest design recommendations. These models consist of shell elements with two rotational springs. Results indicate that current methods for the design of EmBCs are nonconservative.

Motivated by the preceding discussion, this paper presents a study with 3D sophisticated FE models to investigate further the seismic behavior of EmBCs. These models provide insights into the internal stress distribution and patterns of deformation of these connections. The models intend to capture phenomena such as the multi-axial constitutive response of the materials (steel and concrete), large deformations, and the contact between the column flange and the foundation. The paper starts by describing the models developed herein, and then the main findings are presented. Finally, the limitations of the study are discussed, and recommendations for future research are presented.

## 2 EXPERIMENTAL DATA

In this study, for the purposes of model validation, the experimental program conducted by Grilli and Kanvinde [7] at the University of California Davis was used. Thus, in this section of the paper, the details of the experimental program are briefly summarized. All tests consist of a steel column welded to a bottom base plate. The column height was about 3m, and it was embedded into a concrete foundation. All the specimens were subjected to the cyclic loading protocol ATC-SAC (Krawinkler et al. 2000 [15]). The parameters that changed among the tests are the embedded depth, the level of Axial Load (Tensile forces were used in one test), and the column size. Table 1 shows a summary of the test parameters, while Figure 2 a schematic representation of the test setup at UC Davis.
